Subsequently, many attempts have been made to improve the classification of depressive reactions. Some English writers retain the original designation, "involutional melancholia." Henderson and Gillespie, after studying a series of cases admitted to the Glasgow Royal Mental Hospital and to some of the county mental hospitals in Scotland, stated unequivocally that involutional melancholia is a relatively common type of mental disorder, possessing certain features of its own. The American Psychiatric Association gives distinction to a depressive reaction of the involutional years, and yet, as recently as 1952, its Committee on Nomenclature and Statistics revealed doubts about the pathogenesis by listing involutional psychotic reaction as the only psychotic disorder under the etiologic group, "disorders due to disturbance of metabolism, growth, nutrition, or endocrine function."

These nosological ramblings recall Meyer's efforts to delineate the condition as one of the symptomatic depressions with complex etiology. Involutional psychotic reaction finally attained its proper categorization when it was classified under affective psychotic reactions in the last revision of the *Standard Nomenclature of Diseases*.

The Committee on Nomenclature and Statistics of the American Psychiatric Association (A.P.A.) defines "involutional psychotic reaction" as follows:

In this category may be included psychotic reactions

characterized most commonly by depression occurring in the involutional period, without previous history of manic depressive reaction, and usually in individuals of compulsive personality types. The reaction tends to have a prolonged course and may be manifested by worry, intractable insomnia, guilt, anxiety, agitation, delusional ideas, and somatic concerns. Some cases are characterized chiefly by depression and others by paranoid ideas. Often there are somatic preoccupations to a delusional degree.

The cardinal delineating features are: (1) personality predisposition, (2) no previous mental disorder, (3) occurrence within the involutional phase of life, and (4) severe depression with apprehension, agitation, suicidal preoccupation, and profound insomnia, culminating in somatic, nihilistic, and occasionally paranoid delusions.

Epidemiology

At the present time, the most reliable statistics on the incidence of involutional psychotic reaction are derived from studies of first admissions to hospitals. It is impossible to determine the actual incidence rate, since there is no method for constructing statistics for patients who recover without treatment, are treated by a family physician or private psychiatrist, or are handled by many public agencies and clinics. Statistics do indicate steady increase of first hospital admissions with a diagnosis of involutional psychotic reaction. Malzberg reported an increase from 2.4 per cent in 100,000 hospital admissions in 1921 to 6.1 per cent in 100,000 hospital admissions in 1940, and 7.2 per cent in 100,000 hospital admissions in 1950.

Simon, in a study of ethnic groups, reviewed all first admissions to a general hospital facility located in a Southern state over the 5-year period of 1959 through 1963. He found that the incidence of involutional psychotic reaction was higher among white women than among Negro women, but there was no significant difference in the incidence in white and Negro men. He suggested a later survey to determine the effect on comparative incidence rates of involutional psychotic reactions in Negroes due to changing social roles, new civil rights, increased urbanization, and improved education.

From the standpoint of sex and age, Kielholz found that females have a higher incidence of involutional psychosis than males. This preponderance is by a ratio of 3 to 1. He also found the condition to be more prevalent in women between 51 and 60 years of age and in men between the ages of 61 and 65. In a majority of cases, the involutional depression had its onset in females from 3 to 7 years after menopause.

In an analysis of certain socioeconomic and cultural conditions, Frumkin found the incidence of involutional psychotic reaction to be higher in individuals from low income and low prestige groups than among professionals and semiprofessional persons. Formal education was inversely related to occurrence of the

reaction, as was the degree of family organization; there was noted a higher incidence among widowed and divorced individuals. The urban population produced twice the number of first admissions as from rural areas. However, Henderson and Gillespie found that the incidence of first admissions to county mental hospitals was higher than to urban hospitals in Scotland.

Etiology

The mystery of the etiology of involutional psychotic reaction is no nearer solution now than when Kraepelin first singled out the reaction from other depressions. Biological studies offer no real clues as to whether or not human behavior is influenced by changing nutritional requirements, decreasing gonadal hormone secretion, and the altered neuroendocrine and metabolic activity taking place in the involutional years. Other investigators have been more successful by using the techniques of the psychobiological and psychoanalytic schools of psychiatry and of the social sciences to gather information about the psychopathology of individual cases and the social setting contributing to the development of the psychosis.

Premorbid personality types. For years it has been known that certain premorbid personality types are predisposed to develop involutional psychotic reaction. The A.P.A.'s official classification lists the three personality disorders so predisposed as (1) the compulsive personality, (2) the passive-dependent personality, and (3) the passive-aggressive personality.

Compulsive personality. This personality type has the greatest predisposition to develop an involutional psychotic reaction. In a series of patients, Kielholz found traits of the compulsive type in 80 per cent; the remaining 20 per cent were schizoid or tended to be moody and worried. The compulsive personality is defined by the A.P.A. as follows:

Such individuals are characterized by chronic, excessive, or obsessive concern with adherence to standards of conscience or of conformity. They may be overinhibited, overconscientious, and may have an inordinate capacity for work. Typically they are rigid and lack a normal capacity for relaxation. While their chronic tension may lead to neurotic illness, this is not an invariable consequence. The reaction may appear as a persistence of an adolescent pattern of behavior or as a regression from more mature functioning as a result of stress.

Further analysis of individual case histories of the compulsive personality reveals a childhood filled with unusual anxiety and early insecurity. The home atmosphere was tense, frugality was practiced, and the parents were rigid in discipline. This type of child generally had difficulty with interpersonal relationships. As adults, such individuals possess a wealth of strong reaction formations and other personality defense mechanisms to enable them to make a well concealed, neurotic adjustment to life. Consequently,

the compulsive personality has more early life successes than failures and hence will be more threatened by any decline in ability or a possible loss of position.

Passive-dependent personality. This personality type is characterized by helplessness, indecisiveness, and a tendency to cling to others as a dependent child to a supporting parent. In such individuals, life-long insecurity produces timidity, submissiveness, and extreme sensitivity to the moods of others. Many are self-sacrificing, become loyal subordinates, and have a pronounced dependency on the approval and the emotional support of others. Poorly repressed aggressive drives can cause fretfulness and doubt, with great demands on the family and associates.

Passive-aggressive personality. This personality type is denoted by passive measures, such as pouting, stubbornness, inefficiency, and obstructionism. Such persons are overly critical, distrustful, and jealous; they blame other individuals or the environment for their failures. Neither the passive-dependent nor the passive-aggressive personalities have the tempered strength of character of the compulsive personality.

Intrinsic precipitating factors. The intrinsic precipitating factors are intertwined psychodynamic and psychophysiological reactions, although it is known that endocrine depletion and vegetative and metabolic changes do not, of themselves, precipitate an involutional psychotic reaction.

Clinicians have long been intrigued with the relationship of the climacteric to the development of the psychosis, and hormone replacement therapy has been used extensively in the treatment of females. Well controlled research studies have demonstrated that the symptoms and course of involutional psychotic reaction are not influenced by replacement hormone therapy. A typical study is that of Ripley *et al.*, using injectible preparations of estrogen. The experimenters relied on serial vaginal smears to determine the exact dosage necessary to produce the desired physiological restoration of vaginal cytology. Even those patients who proved to have the desired physiological response failed to show improvement.

The first symptoms of involutional psychotic reaction generally begin several years after menopause. It should be emphasized that the involutional phase embraces a period of several years and that the climacteric is only one of many happenings in that period. On the other hand, menopause, with the women's mixed feelings about cessation of menstruation, does have many cultural implications. The phenomenon is associated with loss of the ability to bear children and a threatened loss of personal warmth, sexual desire, and physical attractiveness. In some subcultures, another threat to midlife serenity is the engrained myth that women often lose their minds at change of life.

Men equate failing potency with loss of virility, youthful zest, and the best attributes of manhood. Many men approaching the climacteric develop an

emotional reaction to a feared loss of normal sexual activity.

Psychological hypotheses that attempt to explain the development of a typical premorbid personality and the eventual precipitation of a psychosis are drawn chiefly from the fields of psychoanalysis. In the oral stage, strong mixed feelings of love and hate predispose to the development of a narcissistic personality, which reacts to subsequent disappointments with ambivalent emotions of grief and anger. Hendrick says that the narcissist exaggerates his own importance and is easily hurt by the depreciating opinion or lessened affection of others. He points up that the narcissist's excessive evaluation of self can be seen in the psychotically depressed person who is constantly bemoaning his uselessness, unworthiness, and need for punishment; but such a person betrays a high evaluation of himself in the superlatives used to describe his complaints and in the constant demands he makes on others. Involutional depression, from the psychoanalytic point of view, is the personality's reaction of grief and anger to a real, anticipated, or imagined loss in later life.

Extrinsic precipitating factors. The extrinsic precipitating factors associated with the production of involutional psychotic reaction center on interpersonal relationships, cultural mores, and socioeconomic conditions of that era of life. The sociocultural emphasis in this country is on physical strength, vitality, and the mental alertness of youth. There is little reverence for the wisdom of age. The middle-aged man is well aware of the competition from more youthful men and is deflated by an abrupt realization that the social and economic goals of earlier years can never be realized. Forced or voluntary retirement, loss of a job, and loss of financial independence and prestige become added threats to the economic and social integrity of the individual.

Probably the most traumatic experience for both men and women is the death of a spouse, close relative, or dear friend for whom the individual has a healthy or neurotic attachment. The separation is doubly important if the lost one fulfilled a supervisory role or gave economic support.

For a woman, middle age is the period of life when her children leave home for college, employment, or marriage. An emotional void results for the over conscientious, compulsive housewife and mother who has devoted all her life to her family and failed to establish suitable substitutes. Even the presence of a retired husband in the home, if he interferes with her perfectionistic routine, is sufficient to generate poorly controlled aggressiveness and help precipitate an involutional psychosis.

Occasionally, physical trauma, mutilating surgery, or a physical illness can be identified as a precipitating factor. Minor surgical procedures, especially pelvic surgery in women, have precipitated this disorder.

The assumptions of psychoanalysis attribute high

causality to actual or feared loss of body tissue, loved persons, valuable objects, old pursuits, and personal and social values—all of which may overwhelm the susceptible personality.

Clinical Description

Many authors subdivide involutional psychotic reaction into three types: (1) the depressive type, manifested by severe depression, agitation, suicidal preoccupation, and delusions of guilt and nihilism; (2) the paranoid type, with suspiciousness, marked hostility, delusions of persecution, and ideas of reference; and (3) the mixed type, presenting an admixture of sustained agitation and paranoid ideation. In view of the incidence of the depressive type—80 per cent—the clinical description of involutional psychotic reaction is confined to this variety.

The reaction in the depressive type frequently occupies a prodromal period that varies from weeks to months to years. Occasionally, there is a sudden or even fulminating onset in response to some major precipitating event. Anxiety and apprehension are the core of the prodroma. The patient develops terminal insomnia and feelings of inner tensions; he experiences easy mental and physical fatigability; and the waning of biological drives produces loss of sexual desire and loss of appetite. Apprehension is followed by worry about personal health. The classical tension headache plagues most patients and is described as constant during the waking hours, with a bandlike sensation or a feeling of pressure in the head. Concern about physical health may cause the individual to consult a physician, in the hope that some physical disease is responsible for the general state of ill feeling.

Gradually, the course of the illness becomes an extension of apprehension into despondency, with weeping, loss of interest in activities, preoccupation with trifles, inability to make decisions, worsening of the insomnia, and multiple somatic complaints. The deepening depression may be intermixed with periods of anger and peevishness, and the early restlessness turns into extreme motor agitation.

On mental status examination, the typical patient exhibits a facial expression of the utmost sadness and presents a dejected, distraught appearance. Weight loss is pronounced, so that the patient appears older than his age. Psychomotor agitation can extend to wringing of the hands, pacing the floor, repetitious pleas for help, and episodes of frenzied behavior.

The mental content describes somatic delusions, nihilistic delusions, delusions of guilt, self-accusations, and, uncommonly, paranoid delusions. Bizarre somatic delusions involving all structures of the body and the earlier fixation on bowel function is the forerunner of absurd ideas about the alimentary tract. Delusions of nihilism consist of the denial of the existence of objects, persons, or natural phenomena. Guilt is so prominent that patients berate themselves

for unimportant transgressions in the past and believe they have committed unpardonable sins. Predictions of some horrible personal fate are accompanied by signs of fearfulness; meanwhile, the patient insists that any form of punishment is justified. Self-accusation and self-condemnation progress to the point of desiring relief through death. Suicidal preoccupation, with thoughts of just not waking up in the morning, is common in the prodromal period. Suicide is a threat at all times. The presence of illusions and hallucinations should raise suspicions of an associated early organic brain disease.

The sensorium is clear, but inattention, difficulty in concentration, and poverty of ideation are seen. Retention and recall, recent and remote memory, and grasp of general information are in keeping with premorbid attainments. There is a loss of abstract thinking ability, and insight is lacking. Psychological tests are useful in the prodromal period.

Differential Diagnosis

The diagnosis of involutional psychotic reaction should be made only after finding the positive criteria that delineate this reaction. The predisposition to develop circulatory disturbances, disorders of metabolism and nutrition, and senile neurohistological changes in this age decree that the possibility of acute and chronic brain disorders receive first consideration. The propensity of physicians to think in terms of cerebral arteriosclerosis in involutional age patients and then to make a snap diagnosis of organic brain disease can have unfortunate results. Acute brain disorders—with the picture of altered degrees of consciousness, confusion, delirium, and associated physical and neurological deficits—are well known.

In obvious brain disorders, intellectual impairment is the chief finding. In the early stages, the impairment produces only an alteration of recent memory and easy fatigability. The sensorium needs to be tested repeatedly, and such psychodiagnostics as the Wechsler Adult Intelligence Scale, the Wechsler Memory Scale, and the Bender-Gestalt reveal signs of organicity. More advanced cases lose all recent memory but have a fair retention of past memory and live in terms of early life experiences. The personality dilapidation is revealed through inattention to personal dress, excreta carelessness, and the habit of either deliberately or unknowingly exposing the genitals. Episodes of gross mental confusion occur and may be associated with transitory fearfulness, which becomes worse at night but is not the sustained, constant fearfulness seen in involutional psychosis. Hallucinations and illusions are also episodic, although delusions, especially of the paranoid type, can be persistent.

The existence of more diffuse cerebral pathology produces convulsions and various neurological symptoms and signs. In addition, the physical examination may reveal hypertension, peripheral vascular

disease, or other pathology. Consequently, the differential diagnosis requires a thorough medical, neurological, and neurosurgical evaluation.

The psychotic disorders without clearly defined structural change requiring differentiation are: manic-depressive reaction, psychotic depressive reaction, schizophrenic reactions, and paranoid reactions.

Manic-depressive reaction. If the depressed phase of the manic-depressive psychosis has its first appearance during the involutional period of life, a difficult diagnostic problem results. A careful history may show an early mild depression or an unrecognized episode of hypomania. Many times, there is a positive family history, and further analysis of the premorbid personality reveals an outgoing, extroverted individual with the mood swings of the cyclothymic personality. Similarly, clinical features of the depressive type of manic-depressive reaction show more mental and psychomotor retardation and none of the bizarre delusions or extremes of self-condemnation encountered in the involutional psychotic reaction.

Psychotic depressive reaction. The onset of a first psychotic depressive reaction during the involutional period may present diagnostic difficulties. The history usually reveals a basically well adjusted personality structure that finds the environmental situation so overwhelming that it regresses into a depression of psychotic proportions. There are feelings of intense guilt, suicidal rumination, retardation of thought, and psychomotor activity, in contrast to the agitation of the involutional psychotic reaction, profound insomnia, delusions of a somatic nature and occasional hallucinations.

Paranoid and schizophrenic reactions. Those developing during the involutional era have neither symptoms nor signs of a true depression of mood. The affect reveals either veiled or overt hostility, and the patient reacts directly to their paranoid delusional content. Such a patient is egocentric rather than guilt-ridden and self-punishing, and the premorbid personality type is either schizoid or paranoid. Schizophrenic reaction, schizoaffective type, may exhibit periods of despondency that are secondary to the underlying delusional content. In addition, the patient shows signs of dissociation, mental blocking, some autism, and a global retreat from reality. Introversion, schizoid, and paranoid characteristics are evident in the life adjustment.

Anxiety reaction. This reaction is classified under psychoneurotic disorders and should never be confused with the advanced stages of involutional psychotic reaction. Anxiety is the prevailing emotion in this condition, and the individual has a life-long tendency to overreact to stressful situations. The prodromal phase of the involutional psychotic reaction can be confused with anxiety reaction, but there are fluctuations in the prevailing anxiety of the latter in contrast to the continuous apprehensive depressions of the psychosis.

Prognosis and Treatment

A review of the literature on prognosis in involutional psychotic reaction reveals a startling difference in the results published prior to and since the advent of the somatic therapies. The available treatment measures prior to 1940 were hydrotherapy, occupational and recreational therapy, sedation, supportive psychotherapy, psychoanalysis, attention to the physical needs and nutritional requirements, and hospitalization for prevention of suicide. Under such a therapeutic regimen, a few patients were reported to have recovered in less than 9 months, but the majority of the remissions were in the 2nd to 7th year after the onset of the illness. Kraepelin reported a recovery rate of 33 per cent, and Noyes found a 40 per cent recovery rate within the first 2 or 3 years after onset.

Many writers have attempted to identify factors that are favorable or unfavorable for recovery. There is concurrence that the prognosis is better in the younger, more intelligent patient and whenever treatment is instituted early in the illness. Thus, patients with a rapid onset have a higher recovery rate than those with a long prodromal stage. Patients with signs of pronounced anxiety, severe depression, and extreme agitation have a higher incidence of recovery.

The reaction itself occurs at the time patients are beginning to lose their adaptive capacities, and it follows that individuals with a strong premorbid character structure have the best chance for recovery. Also, recovery is enhanced by the possibility of the patient's return to a wholesome atmosphere that includes family, friends, economic security, and occupational and other pursuits of interest.

The introduction of Metrazol convulsive treatment, followed shortly thereafter by electroshock treatment, has altered completely the prognosis of involutional psychotic reaction. Huston and Locher used electroshock to treat patients with involutional psychotic reactions. They reported an 80 per cent recovery rate with improvement maintained for 3 years, although 11 per cent relapsed at a later date. These patients were given another course of electroshock, with a similar 80 per cent good response. The authors noted that patients with paranoid features had the poorest results; otherwise, they were unable to find factors to explain the original failures or the reasons for relapse. Their experience typifies the incidence of recovery found in other articles published during the past 2 decades.

Electroshock is the treatment of choice for involutional psychotic reaction. The word "shock," with its multiple connotations, has a less sinister meaning to patients than does the term "convulsive," and most patients readily accept this form of treatment. The physical contraindications to its use are rare; even patients with advanced heart disease can be treated in consultation with a cardiologist. Pretreat-

ment anxiety can be diminished by oral administration of a short-acting barbiturate. Intravenous barbiturate preparations that detoxify rapidly, such as methohexital sodium, induce prompt anesthesia and early awakening. Injection of the proper dose of succinylcholine chloride through the same needle prevents fractures.

Patients require careful supervision throughout the electroshock program. Treatments must be spaced properly to prevent periods of confusion, and they should be continued until all presenting symptoms have been relieved. Unilateral electroshock treatment, wherein both electrodes are applied over the non-dominant hemisphere, can be used exclusively or can be interspersed with bilateral treatments to help lessen the memory loss.

Kalinowsky and Hoch report on the use of Indoklon as the primary treatment; other psychiatrists reserve it for electroshock failures. There is insufficient evidence at this time to compare its effectiveness with that of electroshock treatment. The injection of such anticholinergic preparations as atropine sulphate also has been found effective in some chronic patients with paranoid manifestations.

Psychotropic drugs also have a useful place in the treatment armamentarium. Antidepressants as well as tranquilizers have been employed in the treatment of involutional depression. In cases where the clinical picture is dominated by depressive features, antidepressants may be helpful. In cases marked by agitation or paranoid manifestations, tranquilizers of the phenothiazine type are often effective. In mixed cases that display depressive, agitated, and paranoid features, a combination of both types of medication may prove to be valuable.

Lobotomy is indicated in selected patients with involutional psychotic reaction. The electrocoagulation method of Grantham, which destroys the connections to the dorsomedian nuclei of the thalamus, has been the basis of several studies, and the results have been uniformly favorable. Ultrasonic waves and cryogenic methods are also employed to produce focal lesions and interrupt frontothalamic fibers.

The supportive psychotherapy rendered during the illness should be continued into the convalescence, along with vocational and avocational rehabilitative measures. The majority of patients with involutional psychotic reaction are inaccessible to depth psychotherapy. Abraham stated that psychoanalysis is valuable only in cases of depression preceded by definite traumatic events, such as the loss of a loved person. Wolberg agrees that a person with involutional depression is not a suitable candidate for intensive psychotherapy. Moreover, he warns that recalling painful material can become so untenable to the decompensating personality that it may aggravate the illness and cause a suicidal attempt.

All suicidal risk patients should be hospitalized, both for their protection and for definitive treatment.

This also applies to all patients receiving any of the somatic therapies. Hospitalization permits adequate supervision of the somatic treatment schedule, sedation, tranquilization, and nutritional requirements, and the patients will benefit from the milieu program of the hospital. Under these circumstances, most patients recover in a period of less than 2 months.

Suggested Cross References

For a comparison of involutional depression with the other depressive disorders see Sections 17.2 and 17.1 on the psychotic depressive and manic-depressive reactions respectively, in this chapter and Section 32.4 on nonpsychotic cyclical depression and Section 24.2 on neurotic depressive reaction. Other psychiatric disorders mentioned in this section—obsessive-compulsive reaction, schizophrenia, and the organic brain disorders—are covered in greater detail in Section 24.1, Chapter 15, and Chapters 18 to 20, respectively. The reader is also referred to Hendin's discussion of suicide in Section 33.1. For a more detailed discussion of the treatment methods referred to in this section, such as convulsive therapy, drug therapy, and psychotherapy, see Area G, on psychiatric treatment. The sections on neurochemistry and psychopharmacology, Sections 2.2 and 2.3, contain a discussion of biochemical features of depression.

Chapter 18

Brain Disorders. I: Introduction

18.1 INTRODUCTION TO BRAIN DISORDERS

GEORGE L. ENGEL, M.D.

The complexity of the relationships between brain functions and behavior and the multiplicity of factors capable of adversely affecting brain activity make it difficult to establish a satisfactory nosological classification of the organic syndromes. The American Psychiatric Association classification is based on organic etiology, which tends to overemphasize the etiological role of the single organic factor while obscuring the clinical variations determined by involvement of different systems or regions of the brain and by the psychological and cultural background of the individual.

Organic Factors

The organic factors as determinants of the clinical syndrome are relatively nonspecific. The fundamental process in the organic brain syndromes is damage or destruction of neurons. It is this destruction rather than the nature of the noxious process that is responsible for the characteristic clinical picture. When damage is diffuse and widespread, the basic disturbance in psychic function is the same, regardless of whether the underlying condition is heart failure, hypoglycemia, a head injury, bromide intoxication, or diffuse senile degenerative changes. When damage is to systems or regions of the brain concerned with particular psychic functions, this localization, rather than the nature of the organic factor, yields the characteristic syndrome.

Diagnosis

Diagnosis involves two steps. The first step is to establish the syndrome as organic, as distinguished from the functional disorders. The second step calls for the identification of the factors responsible for the neuronal damage. This requires an understanding of the biochemical and physiological conditions necessary for effective brain function and an apprecia-

tion of the pathophysiology of diseases that may directly or indirectly impair cerebral function.

Psychiatric diagnosis. In the organic syndromes due to diffuse cerebral damage, the basic and constant psychological defects, regardless of any other more obvious behavioral or psychological disturbances, are reduction in the level of awareness or in the efficiency of cognitive functions. Reductions in level of awareness include fluctuating attention, inattention, somnolence, and coma. Reductions in cognitive efficiency include defects in orientation, interpretation of sensory input, memory, retention and recall, arithmetical skills, and ability to sustain a mental or motor task and to utilize abstract concepts or effective generalizations.

If specific neural systems or areas are involved, characteristic disturbances, alone or in combination with the above, may be introduced. For example, damage to frontal lobe connections may reduce interest or motivation with relatively less alteration in attention or gross cognitive functions. Lesions of the hippocampal formation may significantly interfere with the capacity to learn and recall new information without comparably impairing the capacity to retrieve and use old memories and skills (the amnesic syndrome, Korsakoff's psychosis). Temporal lobe involvement may contribute dysphasic elements, distortions in sense of self and reality, *déjà vu*, *déjà pensé*, or hallucinations. Involvement of the reticular activating system or diencephalon may induce states of hyperalertness or insomnia or of somnolence and coma.

Medical and neurological diagnosis. Every patient with an organic syndrome requires prompt and thorough medical and neurological study, with particular reference to ingestion of drugs and alcohol and exposure to toxic materials or anesthesia; previous episodes of disturbed consciousness, including syncope, cardiac arrest, shock, stroke, concussion, and convulsions; neurological symptoms and diseases; and every category of serious medical and surgical disorder in which physiological or biochemical processes can directly or indirectly affect adversely the metabolism or structure of cerebral neurons.

Electroencephalographic diagnosis. The electro-

encephalogram (EEG) is an invaluable aid in diagnosing and following the course of the organic brain syndromes. Three types of EEG changes are found, and each correlates well with the underlying cerebral disturbance and the corresponding psychic manifestations.

Sustained slowing. Inadequate metabolism of cortical neurons or of their subcortical driving systems results in sustained slowing of the EEG. Such slowing may be diffuse or focal, depending on whether the noxious influence is effecting the brain cortex en masse or locally. The degree of EEG slowing reflects the degree of damage to the neurons (up to actual cell death) and, when diffusely distributed, accurately correlates with the degree of reduction in level of awareness and of cognitive performance. However, since destroyed neurons do not give rise to any electrical activity, it is possible to have a normal EEG in the presence of serious organic deficit, as when the EEG originates from surviving neurons that are functionally adequate but insufficient in number to sustain normal cognitive function.

Sustained focal slowing of EEG is indicative of localized brain damage and generally suggests a neurological disorder rather than a general process affecting the cortex as a whole. Diffuse slowing with focal accentuation of slowing may indicate a combination of both.

Sustained acceleration. Diffuse moderate voltage to high voltage fast activity (13 to 20 per second) may occur with toxic reactions to certain drugs, notably the amphetamines and quinacrine. High voltage fast activity localized to the frontal areas is characteristic of barbiturate intoxication. Low voltage irregular fast activity is characteristic of the hypervigilant stage of delirium tremens, an alcohol withdrawal syndrome.

Paroxysmal high voltage slow or fast activity and spikes. These are suggestive of a convulsive disorder and draw attention to the organic brain syndromes associated with epilepsy.

Psychological and Sociocultural Determinants

The clinical manifestations of the organic brain syndromes represent a complex combination of two components: the direct consequences of the damage to the brain itself and the efforts of the individual to cope with the resulting defect and with the demands of his environment. The first is manifest in the altered level of awareness, the cognitive defects, and in the consequences of focal damage, as outlined above. The second is complexly determined by (1) the individual's past psychological development and his characteristic patterns of ego defense and

coping style; (2) the psychosocial setting in and the speed with which the illness develops; (3) the nature of the support from family, friends, physician, and the social structure; and (4) the characteristics of the culture in which the patient was brought up.

To a large extent, the patient's behavior is determined by his efforts to avoid the painful affects of anxiety and depression, which emerge when he cannot cope with cognitive demands. The great individual variability of such factors accounts for the extraordinary range of behavior demonstrated by patients with organic syndromes. Manifest behavior, the content of thought, the nature of sense deceptions or hallucinations—in a word, all the more personal characteristics—are determined by such individual psychosocial factors.

Superficially, the organic syndromes may simulate any form of psychopathology, but attention to the basic defects in awareness, cognition, and specific brain functions in combination with the common EEG abnormalities will assure accurate diagnosis in most instances.

Prognosis

Prognosis is dependent on correction of the underlying organic determinants *and* on the nature of the psychological supports and resources available to the patient. When the organic etiological factor(s) can be eliminated before neuron death has occurred, complete restitution of normal function can be achieved.

In the presence of brain damage, transient or permanent, the capacity of the individual to sustain cognitive performance is greatly enhanced by reducing to a minimum the familiar causes of psychological decompensation, with its accompanying anxiety, depression, and disorganization of ego function. Conversely, placing the patient in an unfamiliar environment or confronting him with cognitive tasks beyond his capacity may produce disorderly, defective performance with anxiety, agitation, irritability, anger, or depression (the catastrophic reaction of Goldstein)—a pattern of response from which recovery may be slow.

18.2 ACUTE AND CHRONIC BRAIN SYNDROMES

HENRY W. BROSLIN, M.D.

Definition

According to the American Psychiatric Association's standard nomenclature, brain syndromes are organic mental disorders due to a diffuse impairment of brain tissue function from any cause. *Diffuse* cerebral tissue impairment is said to be necessary to make the diagnosis of brain syndrome. There is an unresolved nosological dilemma on this point, since focalized lesions may produce serious personality and motoric changes, and diffuse lesions may produce only minor deficits and disturbances in sensory and intellectual functions.

Clinical Description

Organic brain syndromes may produce varying disturbances in the patient's mental state in the areas of orientation, memory, intellect, judgment, and affect; psychotic symptoms may or may not be present. In addition to the deficits of the syndrome of organic brain disorder, the patient may have various psychotic and neurotic personality disturbances that are not the result of cerebral impairment but are directly referable to preexisting personality patterns and conflicts or present day life stresses; the disturbances are not necessarily related in severity to the degree of brain damage. These disturbances are interpreted to be defensive, reparative, and restitutional in nature.

Disturbance in orientation. Orientation is most affected in regard to person and place. Because of a lack of lucidity and disturbance in sensorium, there is an alteration in consciousness. The patient may be disoriented and confused and unable to identify the day, time, location, or the person he is talking to.

Disturbance in memory. Memory is more impaired for the recent past than for the remote past. Where memory gaps are evident, as in head injury or subdural hematoma, defects in retention and recall may be demonstrated by questioning the patient about events in his immediate past or by testing his ability to recall objects, digits, or colors after several minutes to an hour has elapsed.

Disturbance in intellectual functioning. Vocabulary is probably the best single index to intellectual ability. Can the patient tell what certain words mean? Other areas to be evaluated are difficulty in comprehension (Can the patient cope with new concepts and abstractions, such as being able to interpret simple proverbs or to distinguish the similarity or difference in words?); difficulty in calculation (Can the patient perform serial subtractions and simple arithmetical problems?); disturbance in general information or knowledge (Who is the President of the United

States?); and disturbance in learning (Can he read and explain a newspaper article?).

Disturbance in judgment. A patient's judgment, as estimated by responses to test questions, may vary in quality from one subject area to another. The examiner must evaluate the accuracy of the patient's perceptions and his ability to take in new information, to correlate facts in a coherent, logical manner, and to make correct inferences from these facts. These powers may affect his skills in problem solving and alter his answers to hypothetical questions, such as, "What should one do if, while sitting in the movies, he is the first person to discover a fire?"

Shallowness or lability of affect. Evaluating mood or affective state is most effectively done by direct inquiry, especially if good rapport can be established between doctor and patient and if the patient's ability to communicate his feelings is not disturbed because of physical or mental disease. The examiner must evaluate the patient's affectivity—that is, the congruence of his affective state with his ideation—and then must validate his responses whenever possible with reports from others. The range of emotional responsivity in organic brain syndromes may vary from severe depression to elated mania. Irritability, paranoid projection, hostility, anxiety, defensiveness, guilt, and other mechanisms may color the affective picture.

Significance of findings. Determining how well the patient can evaluate his own assets and organic deficits requires considerable skill on the part of the examiner, for it has often been observed that the testing of a patient's intelligence and mental status is also a reflection of the examiner's intelligence and sensitivity. It was demonstrated in 1925 by Hollós and Ferenzi that, in addition to the dysfunction caused by organic damage, there were also reparative or restitutive symptoms, such as delusions, hallucinations, and confabulations. The psychological utility of such symptoms is now better understood.

Patients having more or less conscious understanding of their own disabilities may protect themselves from internal and external stimuli that are burdensome or threatening in accordance with their previous personality patterns. Denial of the deficit is basic; evasion, rationalization, dependency, defensiveness, self-protection, and projection are common mechanisms to ward off painful insight. If information input becomes excessive, irritability, rage, and emotional lability may be viewed as messages of distress and as attempts to interrupt the previous painful communicative process. That these attempts at corrective processes are often ill conceived and ineffectual does not alter their intent.

Where only minor organic damage exists, reparative efforts may be extremely successful. This is the basis for optimism in the vigorous application of therapeutic and rehabilitative measures in severe cases. The concept that massive brain tissue loss must necessarily cause deficits that are discernible clinically and by

psychological testing is incorrect. In 1962 Bruell and Albee described a patient with no discernible deficit following hemispherectomy for a tumor.

As brain structure becomes progressively more damaged, the behavioral defenses also deteriorate increasingly, and psychiatric symptoms appear. These reactions may also be viewed as release phenomena of the organic brain syndrome and therefore superimposed on it. They may include psychotic symptoms, such as delusions and hallucinations—distortion of inner and outer psychological realities that are unacceptable to the patient. Symptoms may also vary according to the relative impairment of different cortical areas.

Differentiation between acute and chronic brain syndromes. Brain disorders are classified in the American Psychiatric Association's standard nomenclature as acute or chronic according to the reversibility of the brain pathology and the organic brain syndrome and *not* according to the cause, onset symptoms, or duration of the disease process. This type of distinction between acute and chronic on the basis of *reversibility* is unusual in medicine and may at times be confusing to the student. Temporary and permanent brain damage usually present the same organic mental symptoms. A brain disorder may initially appear reversible and therefore acute, but later it may result in permanent brain damage, so that the diagnosis has to be changed to chronic. Thus, the initial temporary derangement of brain cell metabolism evolves into permanent disruption and death of brain cells. An example of this situation is the brain syndrome due to acute encephalitis that leaves chronic sequelae. Conversely, a long term illness like pernicious anemia may have cerebral symptoms that may be prolonged and are apparently chronic but prove to be reversible with proper treatment. Such a syndrome, though of long duration, is designated acute. Some important differences in the prognosis, course, and treatment of acute and chronic brain syndromes are summarized in Table I.

Differential Diagnosis

A complete history, physical examination, and laboratory study are essential for the proper diagnosis of the etiology and type of brain syndrome. In the presence of organic psychiatric symptomatology, with or without gross physiological signs of systemic disturbance, the physician must consider the common causes, such as head injury; toxic states due to drugs, poisons, or infection; cerebral vascular disease; the convulsive disorders; metabolic diseases; intracranial neoplasms; and the various brain diseases of unknown cause.

Repeated careful physical examinations are essential, with recording of response to stimuli, vital functions, and neurological signs, such as the pupillary state, corneal reflexes, fundi and visual fields, superficial and deep reflexes, and motor and sensory func-

TABLE I
Comparison of Acute and Chronic Brain Syndromes

	Acute (Reversible)	Chronic (Irreversible)
Onset	Most often sudden in onset with rapidly developing impairment of orientation, memory, intellectual functioning, judgment, and affectivity, and with return to normal status when cause is removed.	Unusually long term progressive impairment of orientation, memory, intellectual functioning, judgment, and affectivity, continually worsening in severity. Frequently slow and insidious in onset.
Symptoms	Usually symptoms of delirium but sometimes coma and stupor. Prominent symptoms are most often confusion, disorientations, and clouding of consciousness. May release various underlying psychotic and neurotic reactions.	Usually progressive symptoms of dementia, but sometimes delirium, stupor, and coma intervene. Frequently there is increasing deterioration in interests, self-concern, intellect, capacity to learn, and patient's motivation. May release underlying psychotic and neurotic reactions or cause primary deficits or restrictive defenses.
Etiology	Caused by reversible, temporary, diffuse disturbance in brain function. Often symptoms are associated with a generalized systemic infection; metabolic, cardiac, or toxic disturbance; or head trauma.	Caused by irreversible, permanent, diffuse destruction of brain cells. Often due to insidious chronic brain lesion or to inflammatory, neoplastic, chronic degenerative, or vascular disease.
Course and prognosis	Usually brief but may be prolonged up to 1 month or longer. May end in health and cure, death, or chronic disease.	Usually chronic and progressive, leading to dementia over a period of months to years. Underlying pathology may subside or respond to therapy, as long as there is an irreducible minimum of cerebral tissue destruction that cannot be reversed. Though disturbance may become milder, some sensorium disturbance persists permanently.

tions. Bloody spinal fluid, stiff neck, generalized body flaccidity, and bleeding from various orifices assist in the diagnosis and assessment of the severity of the injury. Useful laboratory procedures are the electroencephalogram, ventriculogram, arteriogram, echoencephalogram, and air encephalogram. At times an Amytal interview may help in eliciting minor deficits.

Acute head injury should be considered not only in the presence of visible damage to tissue, such as laceration, swelling, and hemorrhage in the head area or signs of impaired consciousness, respiration, or circulation, but also where there are other multiple lesions of the body. This is particularly true in vehicular accidents. A history of dizziness, falls, blows on the head, or alcohol ingestion may be helpful in arriving at a diagnosis. In some cases, reviewing the events leading up to the trauma is the best clue to diagnosis, but the services of a forensic pathologist may be required in cases involving poison, air or water blast, or severe electric shock.

Air or water blast accidents producing acute brain syndromes involve principally internal injuries without external evidence of trauma. Internal injury may be present, even though lacerations, burns, and fractures are absent. In these conditions the prognosis and treatment are determined by the extent of pulmonary damage, and treatment focuses on relief of dyspnea and anoxia by the use of endotracheal intubation, oxygen, bed rest, and whole blood transfusions for shock. Electric shock may cause minute hemorrhages in the brain and spinal cord. Loss of consciousness for minutes to hours—even death—may result. In those who survive, there are usually no permanent sequelae, although such transient symptoms as headache, backache (due to small vertebral fractures), fatigue, muscular pain, and tension states may persist. Artificial respiration is the main treatment for the transient cessation of breathing encountered in electric shocks. In view of this, hospitals now require an anesthetist to be a member of the electroshock team where shock is therapeutically administered for depression.

Acute brain syndrome. The early recognition of acute brain syndromes is facilitated by studying behavior by means of the mental status examination and obtaining a detailed history from patient and family. It is important to establish the presence of either a clear sensorium or one that is impaired by organic or emotional factors. It is also important to differentiate between the presenting picture and the ostensible chief complaint, as well as any underlying diseases, particularly when the initial examination involves a comatose, stuporous, or somewhat disoriented patient. Patients manifesting evidence of alcohol or drug intoxication must be differentiated from diabetics or individuals having a subdural hematoma. After the physician has observed and recorded all his findings, he must integrate the data into a meaningful whole in order to deduce the diagnosis, etiology, and treatment.

High on the list of priorities in diagnosing both acute and chronic brain syndromes should be the observation and inquiry into *changes* in the patient's recent behavior, including mood changes, clouding of consciousness, confusion, irritability, disorientation defensiveness, inappropriate humor, sudden rages, and unaccountably irresponsible behavior. Changes in motor behavior may be detected, such as restlessness; clumsiness in walking, eating, or writing; difficulties in articulation; slurring of speech or perseveration; or a decreased tolerance to alcohol.

Chronic brain syndrome. The initial history and physical, neurological, and mental status examinations should follow the same principles as given for the acute brain disorders. Systemic disease must be ruled out, even though the presenting complaint may be psychiatric or neurological. Generally in the chronic syndrome there will be a history of long term progression of symptoms, blunting of interest with a continual worsening of memory, orientation, and intellect. Eventually there results a serious impoverishment in all spheres of cognition.

Owing to the danger of litigation as well as for scientific reasons, detailed studies of the mental status are advisable in cases of head injury, brain tumor, and epilepsy. In patients with mental retardation, cerebral palsy, chronic alcoholism, advancing cerebrovascular disease, head injury, and other neurological diseases, intensive psychological evaluation for rehabilitation purposes is necessary and should be carried out by trained clinical psychologists.

Much progress has been made in the field of psychological testing since Gelb and Goldstein studied soldiers with gunshot head injuries in World War I. In ordinary hospital practice, a complete psychological work-up of organic cases usually involves the following tests: (1) Wechsler Adult Intelligence Scale (WAIS), which is studied for patterning and qualitative values of the responses as well as for statistical score on the verbal and performance parts; (2) Rorschach; (3) Draw-a-Man and House-Tree-Two Person tests; (4) Bender-Gestalt test for organicity; and (5) Thematic Apperception Test (TAT). These tests are helpful in detecting memory defects, confusion, and emotional and intellectual disturbances, often at an earlier time than can a clinical psychiatric examination.

Treatment

In the treatment of the acute brain syndromes, gross physical distress should be eased by means of bed rest, warmth, sedation, and control of hemorrhage. The patient should be made as comfortable as possible by symptomatic, supportive, and prophylactic measures. Because of the danger of respiratory failure or severe hypoxia, emergency measures, such as endotracheal intubation, tracheotomy, and oxygen, may be indicated. Burns, fractures, and lacerations should be treated promptly. Blood loss should be controlled

through whole blood transfusion. Shock or vascular collapse should be treated with plasma and whole blood, and general systemic support should be provided by maintaining fluid and electrolyte balance. Management or prevention of infection is accomplished by the judicious use of antibiotics.

Treatment of chronic brain syndromes is generally symptomatic and supportive and, when possible, is aimed at relief of the underlying disease process.

Suggested Cross References

For more detailed descriptions of the various behavioral symptoms mentioned in this section and of the mental status examination, see Section 13.1 and Section 11.2, respectively, in Area E, on assessment in psychiatry. In that same area, see also Benton's discussion of psychological tests used to assess organic brain damage (Section 12.2). See Section 10.1 for a discussion of the neurological examination, which is also helpful in the assessment of organic brain disorders.

failure of general metabolic support of the brain or to the action of endogenous or exogenous toxic substances that depress cerebral metabolism.

The term "syndrome of cerebral insufficiency" has been proposed to emphasize the similarity to the more familiar concepts of hepatic or renal insufficiency, including the potential for reversibility if the etiological factors are eliminated before cell death has occurred. It includes the toxic psychoses and the infective-exhaustive psychoses of the older literature.

Many instances of delirium are readily classified within the American Psychiatric Association classification of acute and chronic brain syndromes, but more are either the result of multiple factors operating simultaneously or of some inadequacy of systemic systems supporting brain metabolism. As such, they do not constitute discrete syndromes as much as they are the central nervous system manifestations of the underlying systemic disease.

Incidence

The high incidence of delirium is indicated by the fact that it is present in every patient who is approaching or recovering from coma, who is terminal, who is recovering from general anesthesia, or who is drugged to the point of confusion, and it is present in most patients with severe degrees of anemia, fever, peripheral circulatory collapse, cardiac arrest, congestive heart failure, respiratory failure, pulmonary insufficiency, hepatic or renal insufficiency, acidosis or alkalosis, electrolyte imbalance, or infection; it is also present in those suffering from the effects of many different drugs and from the remote effects on the central nervous system of almost every disease in which bodily homeostasis is seriously deranged. A rough estimate suggests that 10 to 15 per cent of patients hospitalized on acute medical and surgical services manifest some degree of delirium. Among ambulatory patients, alcohol and drug intoxication are the most common causes of delirium.

Etiology

Delirium is due to cerebral metabolic insufficiency. This may involve interference with cerebral metabolism because of inadequate delivery of oxygen, glucose, and other essential substrates, damage to transport mechanisms or intracellular enzyme systems, or disruption of synaptic transmission systems or cell membranes.

With the exception of such gross processes as anoxia and hypoglycemia, little information is available concerning cerebral metabolism in situations comparable to those encountered in clinical delirium. Measurements of cerebral metabolism in humans by the Schmidt-Kety technique—a relatively crude measure of O₂ consumption of the whole brain during hypoxia, hypoglycemia, hypothyroidism, diabetic acidosis, and pernicious anemia—reveal significant reduction in total O₂ consumption only when the defect is severe, approaching coma.

18.3 DELIRIUM

GEORGE L. ENGEL, M.D.

Definition

The term "delirium" is used to cover those instances of acute and chronic brain syndromes secondary to

On the other hand, the spontaneous electrical activity of the cortex, as recorded by the electroencephalogram (EEG), provides an accurate reflection of the metabolic adequacy of cortical neurons. Since the rate of firing of single cortical cells decreases progressively with reduction in O_2 and glucose supplies and with cellular poisons, and since the frequency of the EEG reflects the electrical activity of masses of cells discharging synchronously, factors that alter the rate of discharge of individual neurons, such as their metabolism, correspondingly alter EEG frequency. Studies of EEG frequency of humans during exposure to hypoxia, hypoglycemia, carbon monoxide, alcohol, and other toxic substances known to interfere with cerebral metabolism reveal good correlation between the degree of slowing of EEG and impairment of cortical metabolism.

Patients with delirium demonstrate the same correlation. Diffuse slowing of the EEG is a regular finding in delirium, regardless of etiology. The EEG of most delirious patients shows significant activity slower than 8 per second; those delirious patients whose EEG shows no slow activity will be found on recovery to have a high normal (11 to 12 per second) or faster than normal (> 12 per second) pattern. The earliest signs of delirium, whether spontaneous or experimentally induced, correspond with a decrease in mean EEG frequency of 1 to 2 cycles per second. With the more severe disturbance, the EEG regularly slows to below 6 per second, with much irregular (1 to 2 per second) activity in the comatose patient (see Figure 1).

There is also a close correlation between EEG and reversibility of the underlying process. If the metabolic deficiency can be corrected, as by the administration of O_2 to the patient with cardiac failure or of vitamin B_{12} to the patient with pernicious anemia, there is an increase in EEG frequently corresponding with clinical improvement (see Figure 2). Hence the EEG constitutes a reliable indicator of the presence of delirium and of the adequacy of treatment. Failure of the EEG to return to normal means that therapy is inadequate or incorrect.

Clinical Description

The basic disturbance in delirium is a reduction in the level of consciousness, in the ability to attend, and in cognitive function. It is with these properties that the EEG correlates most accurately, being slowest with the greatest reduction in awareness.

The essential requirement for the diagnosis of delirium is a high index of suspicion. Any patient seriously ill with major physiological or biochemical derangements should be considered as possibly delirious, as should any medical or surgical patient who has difficulty in recounting the history accurately or in cooperating with the requirements of the examination. With milder degrees of delirium, even the seriously ill patient can by heightened effort compensate

for defects, but the physician who anticipates delirium in such an ill patient will recognize that the level of attention is fluctuating and that the patient is demonstrating errors in memory and retention and recall, and a decreased ability to concentrate.

The degree of delirium is measured in terms of the level of awareness and not by any other psychical attribute. The extent of manifestly disturbed behavior or of bizarreness of thought content is no measure of the degree of cerebral involvement and does not correlate with EEG slowing. Some patients may traverse the entire range from the subtlest decline in cognitive performance to coma without manifesting any spontaneous behavior that calls attention to the delirium. Others with a relatively mild defect may respond with gross anxiety merging on panic, hallucinations, sense deceptions, delusions, irrational speech, or outbursts of misdirected rage. The first group is frequently not recognized as delirious; the latter—though often misdiagnosed as having schizophrenia, mania, or some other form of psychosis—generally precipitate a psychiatric consultation.

Typical Patterns of Delirium

The quiet, torpid patient. The defect is inapparent except on direct examination or in the course of observing the patient's inability to recognize hospital personnel or visitors, to cooperate in simple tasks during examinations, or to cope with feeding, washing, or excreting. Such patients either deny or try to cover up their difficulties, often saying they are sleepy, weak, or tired.

The blandly confused patient. This person may at first glance appear relatively comfortable and at ease, responding in a friendly, smiling manner, usually claiming to feel well. But if inquiry extends beyond the perfunctory "How are you?" one will note that he responds slowly, uncertainly, and in a limited and repetitious manner without elaboration, often with a quizzical, puzzled expression, and that he tends to deflect inquiries by attempts at humor or by becoming irritable. More direct examination readily demonstrates the disturbances in memory, concentration, orientation, etc. This type of patient is making use of denial to avoid awareness of his cognitive defect and may become appreciably disturbed if he is pressed too hard.

The anxious, panicky patient. This patient is profoundly disturbed by his inability to maintain cognitive control and may respond even to a mild defect with severe diffuse anxiety and even panic. He may manifest restlessness, tremor, rapid heart, hyperventilation, sweating, peripheral vasoconstriction, frequency of urination and defecation, all of which may confuse the clinical picture of the underlying disorder. His mental attitude is one of diffuse apprehension, with exaggerated concern about what goes on about him, a tendency to startle at unexpected sounds, and fitful sleep with frightening dreams. He

FIGURE 1. EEG changes during recovery from severe delirium due to nutritional deficiency secondary to acute and chronic alcoholism in a 28-year old woman. The spectrum indicates distribution of EEG frequencies and shows progressive increase in alpha activity as level of awareness and cognitive function approach normal. (From Romano, J., and Engel, G. L. Delirium. I. EEG data. *Arch. Neurol. Psychiat.*, 51: 356, 1944.)

may attempt a panicky flight from the hospital bed. When the underlying delirium is severe, there is usually no difficulty in recognizing from the patient's spontaneous productions that he is disoriented and grossly misinterpreting events about him. With milder delirium, it is usually possible with patience to calm the patient sufficiently to permit some more direct observation of the cognitive deficit. Too hasty use of sedative drugs before diagnosis is established serves to confuse the picture, since they may induce

or contribute to delirium, even though the anxiety is ameliorated.

The hallucinating patient. He quickly attracts attention to himself. Most often he is misinterpreting sensory experience rather than hallucinating. Sounds in the hall are mistaken for familiar voices, vague shadows and shapes are misinterpreted as familiar persons or objects, the picture on the wall may be seen as a face, the sound of the air conditioner or suction pump may be heard as factory

noises. The content of such sense deceptions reflects intense anxiety in some; in others the deceptions may be reassuring, as when the voice is believed to be that of a loved one or the face on the wall that of an angel. True hallucinations may also occur. Again, attention to the underlying cognitive defect will readily identify the disturbance as delirium.

The muttering, incoherent patient. He is usually experiencing a more advanced degree of delirium. Disorientation as to time and place are generally gross, as are the other cognitive failures.

Examination

With most patients the diagnosis can be made within the context of ordinary history taking and physical examination and without recourse to a specific mental status examination. The following clinical picture strongly suggests delirium. (1) The patient responds slowly and hesitantly and with a quizzical, puzzled expression, even to simple questions. His brow is furrowed, and his eyes turn up or scan the room, as if the answer literally is to be found by looking for it. (2) He attempts to ward off questions by humor, sarcasm, distraction, and depreciation. If pressed, he may become anxious or angry. (3) If the same question is repeated, the response is inconsistent or contradictory. By asking the patient for such verifiable factual information as are customary in a medical interview—dates of onset and duration of illness, dates of birth and ages of patient and family members, address and phone number of self, relatives, and physician—one can unobtrusively check recent and remote memory, orientation, and ability to perform simple calculations. Delirious patients may be able to report birth dates but may be unable or refuse to calculate ages. (4) During the physical examination, the patient may seem confused about directions and need repeated instructions. He may be unable to initiate or to persevere in a requested act, such as to stick out the tongue or extend the hands, reflecting inability to maintain attention to the task. On the other hand, once mastered, he may persevere in the same act in response to a new command. The physician often finds himself speaking louder, as if by so doing the patient will understand better, a response that in itself should make him suspect that the patient is delirious (or hard of hearing).

Differential Diagnosis

Chronic brain syndrome (dementia). This presents the most common problem, though in fact most patients with chronic brain syndromes get significantly worse during a serious systemic illness or with cerebral depressant drugs (notably barbiturates) and hence may be said to have a superimposed delirium. A normal or only slightly slowed EEG in the presence of a gross defect favors dementia. Some conditions, such as pernicious anemia, hypothyroidism, adrenal

insufficiency, and hyperparathyroidism, may exist for months or years misdiagnosed as chronic brain damage yet reverse completely with proper therapy. It is impossible to know how many cases that begin as delirium suffer irreversible brain damage when the underlying defect remains too long uncorrected. Such cases then end up as examples of dementia.

Schizophrenia. Patients with schizophrenia do not show the generalized cognitive defect nor the characteristic EEG slowing of delirium.

Hysteria. The dissociative states, fugues, amnesia, and pseudodementia (Ganser's syndrome) may be differentiated by the fact that cognitive performance is inconsistent, being excellent in some areas and markedly deficient in others. Acknowledged amnesia for one's own name virtually never occurs in the delirious patient. The disorientation as to place or time of the dissociated hysteric is not consistent with his evident alertness and capacity to assimilate new information. The ridiculous responses of Ganser's syndrome ("How many legs does a three-legged stool have?" "Four") require a degree of cognitive efficiency of which the delirious patient is incapable. A history of delirium in a family member often provides the basis for identification manifestations in the hysteric. None of these conditions shows EEG slowing.

Sensory isolation. Sensory isolation—as occurs with covering the eyes after eye surgery or with confinement to the respirator, the Bradford frame, or the oxygen tent and even with isolation for infection—may in susceptible individuals provoke acute anxiety reactions or psychotic behavior. These are not marked by the cognitive defect or EEG slowing typical of delirium and usually respond rather promptly to relief from the isolating situation. It must be underscored that delirious patients also get worse under such conditions.

Prognosis

This depends on the reversibility of the underlying condition and on the capacity of the brain to withstand its noxious influence.

Management

Correction of the underlying biochemical or physiological defect must be carried out promptly if permanent brain damage is not to ensue. The EEG provides an excellent means of following the course of treatment.

Suggested Cross References

The chapter on neurology, Chapter 10, contains further material on the EEG. For information regarding the metabolic requirements of the brain, see Section 2.2 on neurochemistry in Area B, on the basic behavioral sciences. Also see Doty and Smith's sec-

tions on neurophysiology, Sections 2.5 through 2.9, which contain information regarding the localization of the various functions of the brain that were discussed in this section. Organic brain syndromes that are associated with other, underlying disorders are discussed in subsequent sections in this area.

Chapter 19

Brain Disorders. II: Associated with Disturbances in Circulation, Nutrition, and Metabolism and with Unknown Causes

19.1 BRAIN SYNDROMES ASSOCIATED WITH CIRCULATORY DISTURBANCES

EWALD W. BUSSE, M.D., Sc.D.

Organic brain disorders are categorized for nosological purposes into two major groupings—acute and chronic. As has been noted elsewhere in this text, the term “acute” is not used to indicate a sudden onset of the symptoms but to imply reversibility, that is, the later return to normal of the impaired function. Hence, “acute” and “chronic” are terms to describe disease outcome and are not related to onset or etiology. For example, the same etiological agent, embolism, may produce in one individual a temporary or acute malfunction, while in another it may result in permanent malfunctioning, at which time it is considered a chronic disease.

Acute and chronic brain syndromes associated with circulatory disturbances include a variety of specific disorders and syndromes. In this broad spectrum of illnesses are included diseases of intracerebral blood vessels and the extracerebral vasculature, both intracranial and extracranial. In addition, there are systemic circulatory disorders that secondarily affect the functioning of the brain. It is usual to indicate the major site of pathological change by designating the disease an intracranial or an extracranial disorder. This simplified approach to diagnosing disorders of blood vessels has value as it relates to therapy and prognosis. However, the student should be aware that pathology is not limited to the designated blood vessels.

Anatomy of the Blood Supply of the Brain

The carotid and vertebral systems are the two sources of blood supply to the human brain. In most mammals the

brain receives its blood through these two major sources, but wide variations exist among different species with respect to the relative importance of these channels of flow. For example, the brain of the laboratory rodent receives its blood supply chiefly by way of two well developed vertebral arteries, and the internal carotid is of less importance. In other animals, such as the dog and the cat, the major flow is through the external carotids, via a well developed network of anastomoses between the external carotid and the intracerebral circulation, and from the vertebrals; the internal carotids are of minor significance. It is evident that reliable studies on cerebral circulation must be performed on man, or in primates whose blood supply resembles that of man, so that our knowledge of human blood circulation may be increased.

Vertebral arterial system. The vertebral system is a simple one composed of the two vertebral arteries entering the cranium through the foramen magnum, joining to form the basilar artery which passes anteriorly to the level of the midbrain, where it divides into the two posterior cerebral arteries. This system, during its course through the posterior fossa, gives off several pairs of arteries providing the blood supply to the cerebellum.

Carotid arterial system. The carotid system derives from the two internal carotid arteries. On entering the skull, they bifurcate, forming the anterior and middle cerebral arteries and a cross-communication through the anterior communicating artery. The carotid system and the vertebral system also communicate through the posterior communicating arteries, thus forming the circle of Willis (see Figure 1). The circle of Willis is frequently incomplete, but it is the origin of the six main arteries, the branches of which are the source of blood for the brain.

Venous drainage. The venous drainage of the brain is also divided into two systems (see Figure 2). The first are veins arising from within the brain and emptying into Galen's vein and the straight sinus. The second drainage system is composed of veins that lie over the surface of the cerebral hemisphere and which drain through the superior sagittal sinus and the lateral basal sinuses.

The 8 to 12 veins that drain the convexity of the cerebral hemisphere as well as the medial surface flow into the superior sagittal sinus but, before doing so, freely communicate with the deep veins of the brain. These veins form four groups—a frontal, a paracentral, a central, and an occipital group. The middle cerebral vein is responsible for draining the inferior half of the lateral surface of the brain. This vein lies in the fissure of Rolando and empties into the cavernous

FIGURE 1. This drawing shows the cerebral arterial circle of Willis. (From Truex, R. C., and Carpenter, M. B. *Strong and Elwyn's Human Neuroanatomy*, ed. 5, p. 80. Williams & Wilkins, Baltimore, 1964.)

FIGURE 2. The cerebral veins and venous sinuses. The dural sinuses (stippled) and their principal connections with the extracranial veins. (From Truex, R. C., and Carpenter, M. B. *Strong and Elwyn's Human Neuroanatomy*, ed. 5 p. 84. Williams & Wilkins, Baltimore, 1964.)

sinus. It also communicates with the transverse sinus. The venous drainage of the inferior surface of the frontal lobe empties into both the cavernous sinus and the inferior sagittal sinus. Veins on the inferior surface of the temporal lobe divide and empty into the transverse sinus and into the superior petrosal sinus, which in turn flows into the transverse sinus. Drainage of the inferior surface of the occipital lobe is accomplished by the posterior cerebral vein, which joins the great cerebral vein of Galen. The veins emptying

the deep portions of the hemispheres flow into the great cerebral vein of Galen. This is accomplished through the two internal cerebral veins, one deriving from each hemisphere. The cerebellum is drained by two systems, one for the superior surface and one for the inferior surface. The veins of the brain have many and varying connections with extracranial drainage via the emissary veins that pass through the calvarium. The mastoid vein is the most prominent of the emissaries.

Physiology of Cerebral Circulation

The heart and the brain are the two organs most dependent on continuous blood flow for maintaining efficiency of functioning. Interruption of circulation for as little as 5 seconds results in disturbances of consciousness and other neurological signs and symptoms. If the blood supply is interrupted for more than a few minutes, the damage to the brain is irreversible.

Cerebral circulation has been systematically studied for many years. It was first believed that the volume of blood flowing through the brain was fixed, and it was not until the turn of the century that it was recognized that blood supply did vary and that it was influenced by systematic arterial and venous pressures. Only in comparatively recent times have the existence and importance of intrinsic control of cerebral circulation been recognized and studied.

In the adult, age alone does not appear to alter the amount of blood flowing through the brain. It has been claimed that there is a difference in cerebral blood flow between middle-aged and elderly patients, but this is not due to age but is probably related to the presence of pathology. However, it does appear that during the 1st decade of life there is an increased rate of blood flow and that the rate of flow falls until the time of puberty, when it stabilizes.

Cerebral circulation does not seem to be affected by elevation of body temperature. In normal sleep, there is a slight increase in cerebral blood flow, rather than a decrease. Although anxiety tends to increase cerebral blood flow, mental exertion is not accompanied by significant changes in cerebral blood flow or oxygen consumption.

Although a number of factors influence the cerebral circulation, there are only two controlling factors of real importance. The first is the pressure head, the difference between the arterial and venous pressures at the level of the brain; the second factor is the total resistance or hindrance imposed on blood flow by interfering with and reducing the lumen of the vessels in the brain. The first aforementioned determinant is important in disturbances produced by extracranial pathology, while the second is associated with intracranial disease.

Studies on patients with cerebral arteriosclerosis and senile psychosis have demonstrated a significant decrease in the cerebral circulation and the oxygen consumption of the brain when compared to determinations in healthy young men. Hypertension uncomplicated by occlusive cerebral vascular disease is not accompanied by a change in cerebral blood flow.

The brain is not uniformly vulnerable to anoxia; the gray matter of the brain is far more sensitive than the white matter. Within the gray matter itself, there exists variation in sensitivity to oxygen deprivation. Particularly vulnerable are the globus pallidus, visual cortex, and Ammon's horn of the hippocampus. Conversely, the cerebellum, the cranial nerve nuclei (including the cardiac and respiratory centers), and the gray matter of the spinal cord are resistant to anoxic effects.

The major arteries supplying blood to the brain communicate with one another through a system of anastomoses, particularly in the circle of Willis. This arrangement facilitates the development of collateral circulation if it is required. However, there is evidence that under normal conditions little mixing of blood occurs among the various arterial sources within the circle of Willis. Ligation of the internal carotid in young individuals does not reduce brain circulation to a level resulting in neurological symptoms. When one internal carotid is ligated, the pressure distal to the ligature is maintained at approximately half its previous value. This is made possible by extra blood flowing through the circle of Willis. However, this compensation via collateral circulation is not found in elderly individuals, where sclerotic compromise of the circle of Willis reduces blood flow below a sustaining level. The laterality of the blood supply to the brain

does not carry over to the same extent in the cerebral venous system. It appears that approximately two-thirds of the blood sampled in each jugular bulb is of ipsilateral origin with one-third having crossed over from the other side of the brain.

The maintenance of cerebral blood flow above a minimal critical level is regulated intrinsically by changes in cerebral vascular resistance. Fall in arterial pressure can be compensated by markedly reduced cerebral vascular resistance. Serious limitation in cerebral circulation does not seem to result until the arterial pressure falls below a level of 60 to 70 mm. Hg. Although under normal circumstances the cerebral circulation is maintained by intracranial factors, other influences should be considered, such as the viscosity of the blood.

Under usual circumstances, a number of variables operate in narrowing or dilating cerebral vessels. These factors may be classified as neurogenic, humoral, and organic. The evidence for a neurogenic control is fairly clear in a number of lower animals but is far from well defined in man. In contrast, the effect of humoral agents in man is more readily demonstrated. An increase in carbon dioxide tension of arterial blood markedly affects cerebral blood flow. In man the inhalation of 7 per cent carbon dioxide is likely to double the cerebral circulation; hyperventilation produces a marked decrease. The effects of oxygen are quite different. High concentrations of oxygen exert a mild constricting effect; low concentrations of oxygen dilate cerebral vessels. A number of pharmacological agents affect circulation by altering cerebral vascular tone. For example, papaverine produces a modest increase in cerebral circulation, but, regardless of the dosage, it does not approach the effectiveness of carbon dioxide. Other agents, such as nicotinic acid, have been assumed to be capable of producing increased cerebral circulation. Unfortunately, there is little evidence to support this view. Xanthine preparations, such as aminophylline and caffeine, influence cerebral blood flow by vascular constriction.

Pathology of Cerebral Vessels

With advancing age, changes occur in the structure of cerebral blood vessels. "Primary aging" refers to those alterations that result from the passing of time and are not the result of disease or trauma. Generally speaking, changes that are considered to be the result of primary aging are characterized by a thinning of the blood vessel wall. Apparently such changes do not result in neurological complications. Such changes are likely to be observed in the smaller blood vessels during the 5th or 6th decade of life; in the larger vessels it becomes evident between the 6th to 8th decades of life.

Arteriosclerosis, the common pathological change affecting cerebral blood vessels, identifies a related group of pathological changes that are both microscopic and macroscopic.

Atherosclerosis. Generally speaking, atherosclerosis affects the large cerebral blood vessels. This type of pathology is frequently observed where blood vessels branch or curve. This propensity occurs intracranially as well as extracranially. Within the cerebral circulation the most common site for atherosclerosis is in the internal carotid artery at the carotid sinus, the main bifurcation of the middle cerebral artery, and the junction of the vertebral and basilar arteries. In addition, the posterior cerebral artery is frequently involved as it winds around the cerebral peduncles, and the anterior cerebral artery is affected as it curves over the anterior portion of the corpus callosum.

Atherosclerosis results in the vessels becoming tortuous and lengthened. The atheromatous plaques are composed of yellowish material deposited along the internal surface of the artery. Microscopic study not only reveals the deposition of fatty substances but also a thickening and fibrous alteration in the intima, with an increase in connective tissue and capillaries.

Hyaline changes. Hyaline changes are more frequently found in small blood vessels. This type of change is held by some to be a rather gradual one. It is usually associated with hypertension and is characterized by thickening of the vessel wall to the point where the lumen may frequently be obliterated.

Hyperplastic changes. This pathological process involves primarily the smaller blood vessels of the brain. There is a diffuse thickening of the entire wall of the vessel, hypertrophy of the intima, and narrowing of the lumen. This type of change is also likely to be found in hypertension.

Cerebral infarction and hemorrhage. The pathological arteriosclerotic processes described above result in the reduction of the blood supply to the brain, with clinical manifestations that are often designated as "strokes." The term "stroke" is not an entirely satisfactory term, as its specific meaning connotes a sudden and severe attack or event. Strokes, small and subclinical or large and identifiable, are associated with either infarction or hemorrhage. Infarction identifies the pathological events that follow occlusion of the lumen and the shutting off of the blood supply. Infarcts may be small or large, single or multiple, unilateral, bilateral, or widely scattered throughout the brain. When the blood supply is blocked, brain cells are irreversibly injured. Nerve and glia cells die and disappear. Nerve fibers degenerate, and the supporting tissues and small blood vessels are destroyed. This disintegration is called "softening." Over a period of weeks, the debris is removed by macrophages and replaced by connective scar tissue. Small extravasations of blood into the infarction area can make the area red rather than pale. However, red infarcts are not primarily the result of hemorrhage. True cerebral hemorrhages within the brain are usually the result of a break in an artery. Small extravasations arise from ruptures in veins and capillaries. The amount of blood that escapes and its damage to vital centers often make this type of pathology the cause of serious illness.

As mentioned previously, the term "stroke" has relatively little specific meaning. There is a remarkably wide variation in the pattern and severity of strokes. Occasionally, attempts are made to differentiate cerebral ischemic events by designating them "shock," "stroke," "accident," etc. Such attempts at differentiation have value, but it is important to recognize the limitations of various categories, as none have widespread acceptance.

Clinical Description of Cerebral Vascular Disease

The clinical manifestations and complications of cerebral vascular disease can be classified in a number of ways. For example, occlusion of a cerebral artery may result in a loss of a sensory or motor function that does not appear to impair intellectual functioning. However, the loss of the sensory or motor skill may have serious repercussions on the psyche of the patient as a result of attempts to handle the resultant anxiety. It is also evident that cerebral ischemia can result in impairment of intellectual functioning which is not of sufficient magnitude to be considered psychotic.

However, when a widespread disruption of physiological functioning of the brain develops, the following important alterations in the individual's thinking and behavior may be noted: The intellectual functions, including comprehension, calculation, problem solving, learning, and judgment, are impaired. Memory is spotty, and orientation for time, place, and

person is faulty. Emotional responses are sudden, inappropriate, and disproportionate to the stimulus.

The basic clinical picture characteristic of widespread organic brain disorders may be associated with a wide variety of other symptoms. The type and severity of symptoms are not necessarily proportionate to the extent of the physiological disturbance, as they are often influenced by long standing psychological patterns, the environment, and the particular physiological state of the patient at the time the brain disturbance develops. Consequently, the clinical picture is the result of many interacting processes.

Chronic Brain Syndrome Associated with Cerebral Arteriosclerosis

The manifestations of this syndrome range from those brain functions the disruption of which can be recognized by physical examination to those abnormalities observable and identifiable by a systematic mental status examination. Therefore, one would expect to encounter patients who manifest sensory or motor losses but do not show a thinking disorder and patients whose illness is restricted to the impairment of psychological functions with no clear evidence of motor or sensory defects.

Localized pathology

Middle cerebral artery. The middle cerebral artery is the most likely to be affected by occlusion (see Figure 3). It supplies the lateral surface of the cerebral hemisphere, with the exception of the frontal pole, the inferior margin of the temporal lobe, and the superior border of the lateral surface of the hemisphere. The middle cerebral artery has penetrating branches that supply the putamen, the outer portion of the globus pallidus, the upper half of the posterior and anterior limbs of the internal capsule, the body of the caudate nucleus, and the superior portion of the head of the caudate nucleus.

Occlusion of the middle cerebral artery results in the characteristic findings of contralateral hemiplegia, cortical sensory deficit, and hemianopsia. Aphasia is present if the occlusion is on the dominant side of the brain. If it is on the nondominant side, agnosias are noted. When branches of the middle cerebral artery are occluded, characteristic signs and symptoms are produced. Occlusion of the precentral artery, which supplies the operculum and the posterior part of the inferior frontal gyrus, results in weakness of the contralateral face and tongue. If the dominant hemisphere is involved, a motor aphasia may result. The Rolandic artery or the central branch of the middle cerebral artery supplies the major part of the precentral gyrus; blocking of this artery produces a weakness of the contralateral arm and face. Since the distal branches of the middle cerebral artery supply the superior part of the temporal lobe, the parietal lobe, and the occipital lobe, occlusion will produce a contralateral cortical sensory loss and a

FIGURE 3. X-rays of fresh cadaver brains in which cerebral arteries have been injected with radiopaque material. A, injection of anterior cerebral artery; B, injection of posterior cerebral artery; C, injection of superficial branches of middle cerebral artery; D, injection of the anterior, middle, and posterior central arteries. (Courtesy of Dr. Harry A. Kaplan.) (From Truex, R. C., and Carpenter, M. B. *Strong and Elwyn's Human Neuroanatomy*, ed. 5, p. 79. Williams & Wilkins, Baltimore, 1964.)

homonymous hemianopsia or homonymous upper quadrantanopsia. If the dominant hemisphere is involved, sensory aphasia or apraxia may be present. Occlusion of the superficial branches, that is, those covering the cortex, can produce a myriad of symptoms, depending upon the location and the extent of the superficial cortex involved.

The lenticular striate artery, the largest of the striate branches of the middle cerebral artery, is the most frequent site of cerebral vascular occlusion. The inability of the lenticular striate artery to supply its portion of the brain results in a typical hemiplegia involving face, arm, and leg.

Anterior cerebral artery. The anterior cerebral artery originates in the internal carotid and follows the dorsal aspect of the corpus callosum (see Figure 3). The area supplied by the anterior cerebral artery includes branches to the orbital and prefrontal lobes. Branches go to the internal surface of the brain, the paracentral lobule, the main portion of the corpus callosum, and the anterior and inferior portion of the caudate nucleus. The clinical picture resulting from occlusion of the anterior cerebral artery or its branches has not been clearly determined. Frequently there is paralysis and cortical hypesthesia of the opposite arm, and at times there is a weakness of the face. Other symptoms include disturbances in smell,

grasping, and sucking reflexes; incontinence of bowel and bladder; akinetic mutism; and mental changes.

Posterior cerebral artery. The posterior cerebral artery is a part of the vertebral system arising from the basilar artery (see Figure 3). Through cortical branches it furnishes most of the blood supply to the ventral surface of each hemisphere. Near its origin from the basilar artery it gives off deep branches that supply the brain stem, including the red nucleus, subthalamic nucleus, substantia nigra, medial portions of the cerebral peduncle, and deep structures within the brain. Branches penetrating into the brain supply the thalamus, choroid plexus, hippocampus, mammillary bodies, medial geniculate body, part of the lateral geniculate body, the body and posterior part of the fornix, and the inferior part of the posterior limb of the internal capsule.

There are multiple locations for occlusion to take place, and numerous symptoms may develop. Few symptoms appear, owing to the collateral circulation that is possible through the communicating artery and through the pial communications with the middle cerebral artery. Contralateral homonymous hemianopsia with sparing of the macula results from occlusion of the superficial cortical branches of the posterior cerebral artery. Sudden occlusion occasionally produces bilateral temporary blindness. A thalamic

syndrome, involving the development of thalamic pain, results from occlusion of the penetrating branches of the posterior cerebral artery. The thalamic syndrome is usually accompanied by a contralateral hemianesthesia. Occlusion of other branches may produce the red nucleus syndrome, subthalamic syndrome, interpeduncular syndrome, and the like.

Internal carotid artery. Occlusion of the internal carotid artery primarily affects the distribution of the middle cerebral artery. As in many instances, the area supplied by the anterior cerebral artery is spared because of an adequate communication provided by the anterior communicating artery. A telltale sign of occlusion of the internal carotid artery is monocular blindness, fleeting or permanent, involving the eye contralateral to a hemiplegia. This indicates interference with blood flow in the ophthalmic artery, which arises from the internal carotid artery. Occlusion of the internal carotid artery is at least four times as frequent in men as in women. It is also three to five times more frequent on the left side than on the right.

Vertebral artery. Usually there are two good-sized vertebral arteries. If an occlusion occurs in one, the other provides adequate circulation, and frequently symptoms do not result. If symptoms do develop, they are characterized by facial pain, rotational vertigo, vomiting, dysphagia, ipsilateral cerebellar ataxia, Horner's syndrome, contralateral loss of sensation for pain and temperature of the extremities and trunk, and homolateral involvement of the senses on the face. At times cerebral ataxia may be the only sign.

Basilar artery. The basilar artery arises from the two vertebral arteries at the junction of the pons and medulla. Occlusion of the two vertebral arteries frequently produces the basilar artery syndrome. The basilar artery supplies the entire pons and terminates with the formation of the posterior cerebral arteries.

Occlusion of the basilar artery or one of its branches produces variable syndromes. The main findings are signs of bilateral upper motor neuron disease combined with unilateral or bilateral cranial nerve involvement. Rotational vertigo, cerebellar ataxia, sensory deficit, and visual field defects or blindness may also appear.

Diffuse pathology. The diagnosis of chronic brain syndrome associated with diffuse cerebral arteriosclerosis includes minor to severe disturbances in thought and behavior that may be attributed to cerebral anoxia produced by arteriosclerosis. Psychosis due to arteriosclerotic brain disease is a recognized clinical entity, and it constitutes a major mental health problem. In the British literature one finds the diagnostic term "chronic confusional state" rather than chronic brain syndrome, and "arteriosclerotic dementia" instead of psychosis with cerebral arteriosclerosis.

Epidemiology. The appearance of symptoms that suggest a brain disorder resulting from circulatory disease is usually noted between 65 and 70 years of

age. However, the disease may appear in persons as young as 45. It is often difficult to establish a correct diagnosis in regard to underlying pathology. The difficulty in differential diagnosis is complicated by the simultaneous existence of cerebral vascular disease and senile brain changes. Both types of pathology are found in more than 20 per cent of patients with chronic brain disease examined at autopsy. In many state institutions in excess of 40 per cent of the patients admitted are over the age of 60. Of the first admissions, one third are diagnosed as having senile or arteriosclerotic brain disease. Casual review of such statistics over the years suggests that there is an increase in the prevalence of these types of brain changes in elderly people. However, this may not be strictly true. Rather, when the age of the patients is considered, it is clear that people are living longer, and it may be that the same percentage develop the illness at a specific age as in years gone by. It is likely that people are now living longer and therefore developing vascular changes affecting the brain who in the past would have died at a much younger age. If present hospital admission rates continue, senile and arteriosclerotic brain disease may be expected to show an increase of 200 per cent in the number of first admissions to state hospitals by the year 1980. Similarly, it has been estimated that 67 per cent of the patient population in state hospitals will be over the age of 65 by the year 2000.

Clinical description. The accuracy of the description of the onset of chronic brain syndrome with cerebral arteriosclerosis is frequently influenced by the presence or absence of a careful observer. Often the disease is reported as having a rather abrupt onset, the onset being identified by the appearance of an incapacitating symptom. However, careful review of the course of the disease frequently reveals that the patient has had an increase in headaches; has complained of dizziness, faintness, and weakness; and in some instances has reported transient focal neurological symptoms. Memory, particularly for recent events, is impaired, and the ability to make judgments declines. Sleep disturbance is usual early in the course of the disease. As the pathological process continues, the patient continues to narrow his interests and activities and often becomes irritable and restless. Unpredictable and profound fluctuations in mood and inappropriate emotional reactions are frequently reported. As a defense against the loss of various abilities, other manifestations of illness appear, which vary from marked hypochondriasis or serious paranoid features to such acts as genital exhibitionism.

Some clinicians indicate that better than 50 per cent of cases with diffuse cerebral arteriosclerosis demonstrate their first symptoms by suddenly developing a delirious picture in which they are confused, incoherent, and restless and frequently have hallucinations. This delirious picture subsides and

leaves the patient at a considerably reduced functioning level, from which he gradually declines. The view of a gradual decline is challenged by recent investigators who believe that cerebral arteriosclerosis is characterized by episodic decreases in mental capacity, with intervening plateaus often lasting considerable periods of time.

The sudden appearance of a serious or incapacitating symptom is often precipitated by an added mental or physical stress. For example, removal to an unfamiliar environment or the presence of serious infection may precipitate the more serious symptoms. There is evidence that such individuals are functioning at a marginal level, and, when added stress is superimposed, the organism decompensates, and mental symptoms become apparent.

Differential diagnosis. The challenge and frustration of clinically distinguishing cerebral arteriosclerosis from senile dementia, Alzheimer's disease, and Pick's disease has continued for many years. Although examination of the brain at autopsy indicates considerable differences in the pathology considered characteristic of senile brain disease and of cerebral arteriosclerosis, during life it is frequently impossible to distinguish the disorders. This is in part attributable to the fact that both diseases can exist within the same person.

In general, patients with arteriosclerosis do not show the profound physical and mental decay seen in patients with senile dementia. They are less likely to sustain fractures of long bones, are not so often bedridden, and are more likely to complain of headaches and dizziness and to have emotional outbursts. Fainting attacks and convulsions are characteristic of cerebral arteriosclerosis. The memory defect in the senile patient is apt to be diffuse; in the arteriosclerotic it is spotty and fluctuant. Both types of patients fabricate in order to compensate for the deficiency. Senile dementia is more likely to produce alterations in moral standards and sexual indiscretions. If neurological examination reveals brain damage, this is evidence that the disease is of vascular origin.

Alzheimer's and Pick's diseases have a gradual onset and occur at a younger age. Alzheimer's disease is characterized by diffuse intellectual impairment, with a steady progression to profound mental deterioration. Alzheimer's disease does not show periodic episodes of improvement. Pick's disease is also an insidious process, but its clinical course and characteristics are more easily identifiable. In attempting to differentiate the arteriosclerotic paranoid reaction from the paranoid illness without organic brain disease, one important clue is that in the organic patient there is a marked fluctuation in the paranoid expressions and behavior. Patients with psychogenic paranoid reactions can control paranoid thinking in certain situations, but it may be easily uncovered by skillful exploration.

Role of the electroencephalogram as a diagnostic

aid. The psychiatrist has few laboratory procedures available to him to assist him in making a diagnosis. The value of the electroencephalogram (EEG) is often depreciated because there are so few easily recognized pathognomonic brain waves. There is apparently no consistent relationship between different types of dysrhythmia seen in the EEG and specific etiological factors. However, the EEG frequently gives the first indication that the brain is becoming involved in an underlying disease process, be it toxic, infectious, metabolic, cerebrovascular, or degenerative disease. Changes in the EEG can often be demonstrated before there is any change in behavioral or psychological performance and actually precede alteration in the measured total cerebral oxygen uptake. Therefore, in metabolic disturbances, the EEG is often quite useful in following the status of the brain. Disturbances in the EEG may predict the beginning of psychological alteration, and improvements in EEG often precede clinical improvement.

It is rare that a patient with Alzheimer's disease is reported to have a normal EEG. The EEG disturbance associated with this disorder is usually reported as a diffuse slowing, with very few or no α waves. These brain wave records closely resemble those found in senile psychosis. The severity of the dysrhythmia is more closely correlated to the rapidity of the progression of the disease than to any specific clinical picture or to the duration of the illness. The patient's age or the presence or absence of seizures does not influence the EEG. Serial EEGs point to the unpredictability of focal abnormalities as they appear and disappear. This fluctuation in focal disturbances may be of help in differentiating diffuse degenerative brain disease from localized pathology.

Focal EEG abnormalities are commonly found and are of value in many disorders of the brain in which the pathology is localized. However, it is important for the clinician to keep in mind that focal EEG abnormalities of unknown origin and of unknown significance have been repeatedly observed in elderly subjects over the age of 60. Such abnormalities are encountered in 30 to 40 per cent of elderly people without any clinical evidence of central nervous disease. This abnormality is characteristically found in the left temporal area, although this disturbance in a small percentage of cases shows a number of variations as to distribution and laterality. As was previously noted, the exact origin of these foci as well as their significance is not clear. The disturbance in some subjects makes its first appearance in middle age and increases in incidence with advancing age. Clinically, these foci tend to be silent and are not related to cerebral dominance, speech disturbances, seizures, intellectual functioning, or blood pressure. However, there is evidence suggesting that a localized vascular disturbance is responsible for the focal abnormalities. An understanding of this peculiarity

must await further research, but the clinician is cautioned not to attribute greater significance to this type of disturbance than is justified on the basis of current knowledge.

Prognosis. The duration of the illness from date of onset is difficult to determine. The average appears to be somewhere in excess of 4 years. However, because of the constant introduction of new medications that prolong life but do not relieve mental symptoms, the lengthening of the life span of these patients is actually producing a serious nursing problem. It is not unusual to find patients who have survived 16 years or longer in a state of severe dementia. Death usually results from overwhelming infection, extensive brain hemorrhage, or myocardial infarction.

Treatment. A number of misconceptions regarding health and the utilization of health facilities are encountered in our society as regards the utilization of state hospitals for the care of the aged. Such distorted attitudes and beliefs are often shared by members of the health professions who are insufficiently informed. These attitudes permeate and influence the care provided for the patient, as they interfere with the cooperation with family, community agencies, and legislators. For example, there is the distorted belief that many elderly people are placed in state hospitals because they are rejected by their families or friends and that many patients with mild organic brain disorders are institutionalized because their families are not interested in taking care of them. In a careful study of the utilization of state hospitals in New York, Goldfarb concluded that their elderly patients are likely to have organic brain syndromes and that they "are not persons who have been rejected by their families for social or financial reasons. They are sick people who need comprehensive medical care and for whom no other adequate community facility is yet available." It is likely that such elderly persons would benefit from care in institutions that maximize the opportunity for continuing relationships with family and friends, but such institutions are practically nonexistent.

Patients who have evidenced signs and symptoms of arteriosclerotic brain disease respond to a carefully regulated pattern of life. If they can be assigned tasks that are in some way rewarding to them and within the limits of their abilities, then irritability, overt manifestations of hostility, and depression with possible suicide may be prevented. As in all diseases, nutrition must be carefully maintained, alcoholic intake should be prohibited, and drugs that affect the central nervous system should be utilized with considerable caution.

In the constant search for new treatments, the hyperbaric method offers a new dimension of enormous importance. This technique provides a method of increasing the quantity of oxygen delivered to the cells of the body and to the brain. Hyperbaric therapy

is not actually new; for over a hundred years, pressure chambers utilizing room air have been used sporadically in Europe. The resurgence of interest is in part attributable to the combining of hyperbaric environmental conditions with the breathing of pure oxygen. Under hyperbaric conditions the remarkable increase in oxygenation is due in most part to the increased quantities of molecular oxygen physically dissolved in plasma, and not to improving the hemoglobin carrier system. This has led to speculation that it would be quite possible to sustain life with little or no circulatory activity. However, since the therapeutic usefulness of increased oxygen would be most effective in the treatment of disorders of the central nervous system marked by inadequate oxygen transport and defective oxygen utilization, it would provide no therapeutic relief of those disorders partly or totally related to an inadequate supply of nutrients or to the inability to eliminate toxic metabolic products due to failure of the circulatory system. Although it is possible that hyperbaric therapy may provide a method of relieving oxygen deprivation within the central nervous system, it is also obvious that there are many complications to be overcome and that considerable research will be needed during future decades. The role of hyperbaric therapy in cerebral vascular accidents is uncertain, since much depends on the ability of oxygen to diffuse through brain tissue. Much more information must also be added to the experience gained with deep sea divers and caisson workers before sufficient data are obtained so that one can appreciate the effects upon the doctors or nurses living or working in a hyperbaric environment.

The resistance of cerebral blood flow to modification limits the ability of drugs in increasing cerebral circulation. Blood flow to the brain is less readily influenced by drugs than it is in any other tissue. No spectacularly useful drug is now available for enhancing cerebral circulation. The stability of brain circulation accounts for the fact that drugs employed for other types of therapy rarely have serious deleterious effects on the blood flow to the brain.

Extracranial arterial occlusive disease producing cerebral vascular insufficiency. It has been known for over a hundred years that cerebral vascular insufficiency can be produced by extracranial arterial occlusive disease. However, within the past 10 years a substantial number of patients (as many as 25 per cent) have been identified whose brain disorders are the result of pathology in the extracranial arteries supplying the brain. Many of these lesions are surgically correctable. The pathology encountered in these patients is usually the result of atherosclerosis, but a few cases can be attributed to a nonspecific arteritis. However, much work has yet to be done before a complete understanding is achieved concerning the relative importance of the clinical history, symptomatology—particularly its effect upon the

brain—and demonstrated disease. The complexity of the disease process adds to the difficulty of diagnosis, treatment and prognosis, since total occlusion in a major vessel can be present without affecting the brain, provided the collateral blood supply is adequate.

Clinical description and diagnosis. Clinical manifestations of extracranial occlusive disease vary widely. They range from minimal and transient visual disturbances, vertigo, and sensory and motor defects to complete hemiplegia. Diagnostic procedures require particular care. The physical examination, particularly the presence of a bruit, is often of considerable help. Carotid compression to precipitate transient neurological symptoms is recommended by some. Others consider it dangerous while believing ophthalmodynamometry and electroencephalography to be of value and the use of arteriography necessary for accurate clinical diagnosis. Because of the high frequency of multiple arterial involvement, it is important to consider visualization of all vessels by arteriography. Most patients should have bilateral carotid and transsubclavian-vertebral arteriography. Thoracic angioaortography should be performed on patients presenting evidence of involvement of the proximal great vessels. Such patients manifest absence or diminution of pulsations in the neck or arms, reduction or absence of blood pressure in the arms, and systolic murmurs at the base of the neck or in the subclavian region.

Treatment. Operative intervention is, as would be expected, of greatest benefit to patients with transient cerebral ischemia. It is also of value to those showing progressive neurological involvement. It is of least value to individuals who have suffered a "complete" stroke. Since prevention of cerebrovascular lesions is not always possible, the rehabilitation of the patient is of utmost importance. In addition to physiotherapy, language retraining, and the like, the motivation of the patient must be given constant attention. The patient's efforts to improve should be encouraged, and the patient must be aware that by such effort he can regain a degree of independence, self-respect, and self-esteem.

Acute Brain Syndromes Associated with Circulatory Disturbance

Under this heading are discussed those impairments of brain function which are due to disturbances within the circulatory system and which are temporary and reversible. However, it departs in a minor fashion from the ordinary definition of the term "brain syndrome" in the standard nomenclature, because it is not restricted to diffuse impairment of brain function. Included here are transient focal brain disturbances. The etiologies of many of these acute disorders are similar to those of chronic brain syndromes. The characteristic of being temporary and reversible is influenced by a number of factors, including the active intervention of treatment and the ability of

the brain to develop a compensatory mechanism of collateral circulation rapidly.

Cerebral embolism. The embolus that lodges in the brain is usually a fragment of a thrombus or clot that has broken away from a thrombus within the heart. Embolism due to air and tumor cells and fat emboli also occur. Embolic phenomena occur rapidly, and usually there is not sufficient time for adequate collateral circulation to be established. Consequently, sparing of brain tissue distal to the site of embolic occlusion is not so common as in thrombosis. No region of the brain is safe from embolic insult, but the area most commonly involved is that supplied by the middle cerebral artery. Almost any kind of heart disease can be associated with embolus, the most common cause being chronic atrial fibrillation, which is caused by atherosclerotic or rheumatic heart disease. It is also possible for emboli to result from paroxysmal auricular fibrillation. Air bubbles which are occasionally present in the systemic arterial circulation as the result of surgical or accidental trauma of the chest can result in cerebral embolism. Fat emboli are actually fragments of bone marrow which usually enter the blood stream following a fracture of a long bone; these latter fractures are particularly dangerous, since it has been estimated that 75 per cent of such cases are accompanied by some type of embolic phenomenon. Less than 5 per cent are fatal.

The clinical picture that results from an air embolus is dependent on the size of the embolus and the area of the brain involved. The type of embolus does not usually play a significant role in the development of the clinical picture. However, air embolism is more likely to be ushered in by the development of visual disturbances, caused by air circulating in the retinal vessels. Such patients are also likely to have nausea, dizziness, and headache. Fat emboli usually do not occur until 2 or 3 days after an injury or operation. As the fat particles pass through the circulatory system, pulmonary symptoms may appear first, with chest pain, coughing, and dyspnea. This is followed by restlessness, confusion, and delirium. If death does not occur by the 6th or 7th day, most patients recover rapidly, with the evidence of brain involvement subsiding over a number of hours, often overnight.

Air embolism may also be a complication of decompression disease. The treatment of choice is immediate removal to a decompression chamber that is a hyperbaric unit where the excess nitrogen dissolved in the blood can be gradually eliminated by the systematic progressive reduction in the atmospheric pressure.

In early stages cerebral symptoms resulting from thrombosis may be more transient and acute than those resulting from cerebral embolism. In a high percentage of patients who manifest or develop a stroke due to cerebral thrombosis, there is a history of fleeting warning symptoms. This can be attributed to the gradual narrowing of the lumen of the blood

vessel and other compensatory devices that make the transient symptoms possible. Such symptoms often have localizing significance; such as brief periods of speech disturbance or weakness of the limbs. Headache and transient disturbances in cognition are also common.

Hypertensive encephalopathy. This condition occurs in patients with severe hypertension. It is usually associated with essential hypertension, but it may be secondary to increased blood pressure as the result of renal disease, pheochromocytoma, Cushing's syndrome, or eclampsia. The exact cause of this syndrome is not definitely known, but it appears to be related to changes that take place within the smaller blood vessels. Examination reveals an elevated spinal fluid pressure and numerous eye changes, including papilledema, hypertensive retinopathy, and retinal hemorrhages. At postmortem examination the brain is edematous, and there are multiple small hemorrhages throughout the parenchyma. Microscopic examination reveals that small vessels have undergone necrotic arteritis.

This condition usually is ushered in by severe generalized headaches, nausea, and vomiting, followed by restlessness and mental confusion progressing to stupor. Convulsions are common. Treatment of this serious disorder includes controlling of the convulsions by the use of intravenous diphenylhydantoin (Dilantin) or barbiturates and measures to lower the blood pressure. In individuals with moderate hypertension who exhibit a relatively mild type of reaction, caution should be shown when lowering the blood pressure because dropping blood pressure too rapidly may precipitate a cerebral infarction.

Cardiac decompensation. In most cases of this type, cardiorespiratory failure has been observed prior to the onset of delirium. In addition to the delirium, the patient appears to be severely ill, and orthopnea is present. The signs and symptoms of circulatory failure are the primary basis for the diagnosis. Circulatory failure may not be the sole cause, and the stasis of the blood within the brain may enhance the effects of drugs, thereby increasing the mental symptoms. Although congestive cardiac failure is the most frequent cause, endocarditis with cerebral emboli can produce the same clinical picture. Improvement of circulation with supportive measures is the basic treatment plan.

An acute brain disorder may have prolonged adverse effects on psychological functioning which are often overlooked. Guilt and embarrassment resulting from his behavior or the thoughts he expressed during the episode often produce serious concern in the patient. Anxiety arising from this source must be recognized and relieved.

19.2 BRAIN SYNDROMES ASSOCIATED WITH DISTURBANCES IN METABOLISM, GROWTH, AND NUTRITION

• EWALD W. BUSSE, M.D., Sc.D.

Senile Brain Disease

Definition. In senile brain disease, also referred to as senile dementia, the symptomatology may vary from mild to severe. It is characterized by a progres-

sive organic deficit, usually occurring between 60 and 90 years of age.

Epidemiology. One of every four first admissions to public mental hospitals is a patient 65 years of age or over. Of these elderly first admissions, 80 per cent or more are diagnosed as having senile brain disease or arteriosclerotic brain disease. Because of the clinical limitations in accurately determining the diagnosis, autopsy material is believed to be more reliable. On this basis it appears that 45 per cent are ill primarily because of cerebral arteriosclerosis, 35 per cent are suffering primarily from senile brain changes, and 20 per cent have evidence of both pathological processes.

In contrast to cerebral arteriosclerosis, senile brain disease is believed to be more common in women. It is usually reported that the ratio of women to men is 2 to 1. The age of onset is somewhat later than that encountered in arteriosclerosis, as it rarely occurs before the age of 65.

The ecology of the chronic brain syndromes associated with old age is of particular interest. The studies that have been reported over the past 15 years generally support the observation that there is a high correlation between socioeconomic status and organic psychosis of the elderly requiring institutionalization. Low socioeconomic status apparently predisposes patients to early onset of severe brain changes. There is also a relationship to educational level, major occupation, urban areas of high concentrations of multiple-family dwellings, and persons living alone. A study concerned with declines in intellectual function in normal elderly subjects, rather than in those with a diagnosis of organic brain syndromes, also points to a relationship between social, physical, and mental status. Subjects occupying a low socioeconomic status are more likely to develop physical disorders, and they show a faster and earlier decline in intellectual functions. The reverse is true of people in higher economic brackets: they are relatively better off physically and do not undergo a serious decline in intellectual skills.

Etiology. There is no explanation for this disease that is sufficiently supported by scientific evidence to justify a firm statement of probable cause. Metabolic, endocrine, and vascular factors have been implicated, and genetic determinants are likely. There exists an obvious need for intensive investigations to establish the cause of senile dementia.

Pathology. The pathological process resulting in senile dementia is not adequately understood. The anatomical changes that accompany the disorder are characteristic, but some pathologists believe that senile dementia and Alzheimer's disease are one and the same disease process. There is some evidence that heredity is a predisposing factor and that this factor is a metabolic defect. Clearly, the pathogenesis has not been firmly established, and controversy continues.

Gross examination of the demented brain shows generalized atrophy, usually most obvious in the fron-

tal lobe. Accompanying the shrinkage of the cerebral cortex and the widening of the sulci is a light or moderate fibrous thickening of the pia-arachnoid.

Microscopically, senile plaques are a characteristic finding. It is true that such plaques can be found in the apparently normal aged, but in senile dementia they are present in greater abundance and size. The view promulgated many years ago that there was no correlation between mental deterioration and the number of senile plaques is not generally true. Senile plaques appear as rounded or oblong argentophilic, granular masses with irregular radiating fibrils coming from the center of the mass. Such plaques occur in any part of the cortex and in the basal ganglia and hippocampus. Senile plaques are quite rare in the white matter.

Another feature is the scarcity of ganglion cells. The degenerating ganglion cells are seen as shrunken or vacuolated, and they often contain lipid deposits. Neurofibrillary changes that are difficult if not impossible to distinguish from those found in Alzheimer's disease are present and are the basis for maintaining an association between these two syndromes. The pathological picture is further complicated by atheromatous changes in many of the large blood vessels.

Clinical description. The changes associated with senile dementia and cerebral vascular disease are frequently present in the same brain. Hence, the clinical picture is apt to be a composite, and the diagnosis is determined by the major signs and symptoms.

Senile dementia is accompanied by other evidence of exaggerated aging affecting the entire body. There is a general wasting of muscles, shrinkage of the soft tissue, loss of elasticity of the skin, thinning and graying of the hair, and easy fatigability. Gait is unsteady, and speech disturbances are common. The course of the illness, with progressive mental and physical decay, may extend over a considerable period of time. The time from onset of symptoms until death can in rare instances be as short as 1 year, but it is common for the illness to be present 10 years or more before death intervenes. Because of the patient's unsteadiness of gait and muscular weaknesses, he is apt to fall and complicate his difficulties by fracture, particularly of the neck of the femur.

Minimal changes are manifested by a self-centering of interest, emotional instability, and difficulty in understanding, properly responding to, and remembering new experiences. Deterioration of some intellectual functions may be minimal, but superimposed on this organic state are previous personality characteristics. The exaggeration of the prior psychopathology accentuates psychotic, neurotic, or behavioral reactions. The exacerbation of these symptoms may be the cause of the more disturbing symptoms.

Attempts have been made to separate patients with senile dementia into relatively distinct diagnostic categories. Such grouping has relatively limited value, as the symptoms characterizing each category do not

seem to be the result of organic change but rather are attributable to the emergence of long standing personality difficulties or patterns of adjustment.

Approximately 50 per cent do follow a pattern of simple deterioration. Why this large segment shows little more than intellectual deterioration is open to speculation. No dramatic events accompany this mental decline, and, because these people do not produce a disturbance in the community or disruption in the family, many of them are not brought to the psychiatric hospital until they have reached an advanced stage of senile mental deterioration.

However, the other half of the patients with senile dementia present complications that include depression, agitation, and paranoid- and schizophrenic-like symptoms. Paranoid reactions are the most common, constituting 15 to 25 per cent of the diagnostic category. Paranoid features may aggravate a family situation since the patient becomes suspicious of his family and often reverses commitments he had previously made in good faith to them. For example, he may change his will and do other things upsetting to those around him.

If the paranoid patient is to be placed in the diagnostic category of organic brain disease, one has to demonstrate evidence of impairment of intellectual function, that is, a decline from a previous higher level of performance. A paranoid reaction is more likely in a person who in his premorbid adult life was sensitive, suspicious, and likely to blame others for his failures. In the advancing years of his life, he interprets socioeconomic changes as events directed against him rather than as an inevitable pattern of social change. In addition, he does not accept or recognize physical changes and their accompanying disabilities. He often feels that measures are being taken against him to frustrate his attempts to utilize his abilities or to attain those rewards that are rightfully his. A significantly high proportion of the paranoid reactions of old age are coupled with serious defects of vision or hearing. The impairment of hearing is actually more disruptive to the personality than visual loss. This loss in perception, when coupled with social isolating factors, undoubtedly adds momentum to the development of paranoid thinking. The clinical picture of the aged paranoid is colored by features that are rooted in the insecurity, loneliness, fears, and unfulfilled wishes of old people. Paranoid reactions are more likely to occur in women than in men. Their delusions are apt to be concerned with poverty, money, hostility of neighbors, and the sexual designs of men.

Differential diagnosis. Differential diagnosis revolves primarily around the differentiation of senile dementia from cerebral arteriosclerosis, Alzheimer's disease, and Pick's disease. The similarity and contrasting signs and symptoms of senile brain disease and cerebral arteriosclerosis are discussed in the section dealing with cerebral vascular disorders. One of

the major distinguishing features involves age of onset. Alzheimer's disease begins before the age of 60, often as early as 40 years. A complication of differential diagnosis that has important treatment implications is the necessity of distinguishing a depressive reaction complicating senile dementia from involutional depression. An accurate history is particularly relevant, and psychological testing can be of help. In senile brain disease the electroencephalographic (EEG) finding is seldom normal, usually consisting of diffuse slowing with diminution or absence of α waves. This finding is not specific for senile dementia; it occurs in Pick's and Alzheimer's diseases as well.

Management. The psychotherapeutic measures usually employed for younger adults are of little use in many institutionalized elderly patients. Supportive psychotherapeutic measures restricted to contact with the psychiatrist are not sufficiently remembered to be carried over into the living experience of these patients. Therefore, if one expects to alter affect and behavior, it is necessary to provide continuing supportive measures in the patient's milieu. Routine patterns of living provide a measure of security, but routinization should be limited to the major events, and efforts should be made to vary constantly the intervening daily activities so that they provide both mental and physical stimulation. Objectionable behavior and the expression of exaggerations should not be ignored; they should be discussed with the patient and placed in proper perspective. Group meetings with patients with organic brain disease are valuable measures if the psychiatrist participates actively, frequently instructing as well as maintaining focus and balance. Statements made by the patients in such a meeting can often be clues to insights which result in better ward management.

Many elderly patients who have mild organic brain disease are helped by psychotherapeutic measures. To develop insight is not the objective; rather it is to have the patient feel that the psychiatrist is an authority who will help him upon request, yet is permissive and nonpunitive. In such circumstances, it appears that the elderly patient gains the most from the feeling that he has the power to protect himself by utilizing the therapist rather than from the feeling that he is liked by the therapist.

No specific treatment is known for the prevention or reduction of the pathological changes underlying senile dementia. Many approaches, including inhalation of oxygen and administration of respiratory enzymes, vitamins, and cerebral stimulants, have been given credit for improvement, but none have been of sufficient therapeutic value to become established treatments. In recent years ribonucleic acid (RNA) has been given orally and intravenously in the hope of restoring intellectual skills. This treatment has shown little promise, but the use of agents that stimulate RNA production appears to hold greater promise. It is

possible that the administration of RNA or a stimulating agent can be of greater use as a preventive measure than as a form of treatment.

Presenile Brain Diseases

Definition. The presenium is a chronological period described by different authors as being between the ages of 40 and 65. In the psychiatric literature, Alzheimer's disease and Pick's disease are frequently designated as presenile brain disorders since both are chronic brain diseases which occur during the presenium and manifest certain clinical features which closely resemble each other and are similar to those encountered in senile brain disease.

It should be noted that in the standard nomenclature of the American Psychiatric Association (A.P.A.), presenile brain disease (with Alzheimer's disease as an example) is classified as a disorder associated with disturbance of metabolism, growth, and nutrition, and Pick's disease is classified as a disorder associated with unknown cause, although, in fact, the causes of both of these diseases are unknown.

In this textbook Alzheimer's disease and Pick's disease will be discussed under the designation of presenile brain disease, and because of their close clinical similarity to senile brain disease will be described with senile brain disease. While this arrangement will then place all these entities under the section, the "Brain Syndromes Associated with Disturbances of Metabolism, Growth, and Nutrition," there is no evidence that any of these diseases are, in fact, due to such disturbance.

The student should be aware that this classification of presenile brain diseases is somewhat at variance with the A.P.A.'s standard nomenclature, which unfortunately is not clear about these aforementioned points.

Pick's disease

Definition. The designation of this disease is a tribute to Arnold Pick, who first published his work in 1892. Pick's original purpose was to illustrate the different types of aphasic manifestations that can occur in senile brain disease. It was really the efforts of other writers that established Pick's disease as a specific degenerative cerebral disease. Although Pick's disease is generally characterized as a senile dementia, it is doubtful that this classification is anything but misleading, as the disease does not appear to be the result of the premature onset of an aging process. Presenile refers to the time of onset, the age of onset being as early as 40, and the average age being 54.

Epidemiology. Pick's disease is rare, being much rarer than Alzheimer's disease, the other presenile dementia. The incidence and prevalence of Pick's disease in the general population is unknown. It constitutes a very small percentage of the autopsy material

encountered in mental hospitals. The female-male incidence ratio is 2 to 1.

Etiology. There is considerable evidence in the literature that Pick's disease is a specific heredodegenerative process that is *not* associated with rapid progression in the normal aging process. A significant number of families suffering from Pick's disease have been reported, leaving little doubt that the condition within these families behaves like a Mendelian dominant trait.

Pathology. The morbid anatomy reveals atrophy involving both gray and white matter in one or more lobes or parts of the brain, resulting in a brain weight less than normal. The area most frequently involved consists of both frontal poles and other parts of the frontal lobe, but not the precentral convolution. The second most frequent involvement is the anterior portion of the insular and the corpus callosum. It is usually more pronounced on the left than on the right. The third most frequent area affected is the temporal lobes bilaterally. In the temporal involvement, the second and third convolutions are usually affected. Occasionally, combinations of frontal and temporal atrophies are encountered, and very rarely atrophy is limited to the frontal lobe on one side. The usual pattern, apparently, is for the process to appear first in the frontal or temporal lobes and later in the parietal occipital lobes and the basic ganglia.

Microscopically, the atrophic areas reveal a loss of nerve cells, with serious disorganization of the normal cellular lamination. Close inspection of nerve cells reveals that there is atrophy of the cell body, pyknosis of the nucleus, and a distinct type of neurocellular degeneration characteristic of Pick's disease. The typical Pick cell is swollen, enlarged, and round in shape. Nissl bodies have disintegrated, and the cytoplasm is homogeneous in appearance. In the cytoplasm there are peculiar inclusion bodies the size of the nucleus of the cell and often larger. This enlarged cell, although an interesting finding, is not always found in the atrophic cortex of Pick's disorder. Iron pigment deposits are found not only in the atrophic areas but also in other areas of the brain. As cells are destroyed, they are replaced by glia. Blood vessels show no changes, and, as a rule, the senile plaques of senile dementia and the neurofibrillary changes of Alzheimer's disease are not found in Pick's disease. Figure 1 shows the distribution of cytoarchitectural changes in a case of Pick's disease.

Clinical description. Consistent with the description of the pathological progression, the illness itself is seen as a slowly progressing dementia, and the symptoms that develop are mainly those associated with the focal cortical lesion characteristic of this disorder. The symptoms resulting from the focal lesions are primarily aphasias, apraxias, and agnosias. The insidious intellectual impairment is characterized by distractibility, easy fatigability, and a peculiar ina-

FIGURE 1. Distribution of the changes in the cytoarchitectural fields of Brodmann in a typical case of Pick's disease. The drawings show the lateral surface (a), the medial surface (b), and the temporal lobe (c). The black areas denote severe changes, the gray areas moderate changes, and the white areas mild changes in the cytoarchitectural fields of Brodmann. (Courtesy of Scharenberg, K., and Waggoner, R. W.)

bility to deal with new problems and situations other than those that are quite simple. In the early stages, memory is not significantly involved, but the attention span is progressively affected and this, in turn, is followed by a decline in memory. Depressive states are rarely encountered, and the affect of the patient is flat. As deterioration continues, restlessness, aimless activity, and senseless talkativeness can develop. Speech is meaningless and hopeless jargon. There is intellectual deterioration, with early loss of abstract thinking. Mild euphoria is occasionally encountered

rather late in the disease. Hallucinations, delusions, and confabulation do not occur in Pick's disease. In the final stages of deterioration, paralysis, contractures, and epileptic seizures are often present.

Differential diagnosis. In distinguishing Pick's disorder from other organic progressive dementias, one must take many factors into account. Of particular importance is the early onset of the disease, the possibility of hereditary features, and the characteristic signs and symptoms of focal cortical damage, usually frontal or temporal. It has been reported that some patients develop peculiar attacks of muscular hypotonia. Epileptiform seizures that develop rather late in the course of the disease are of little diagnostic value. The mental symptoms of apathy, inattentiveness, and a total lack of insight are useful diagnostic features. The electroencephalographic findings are those characteristic of all the senile dementias.

Prognosis. Pick's disease lasts from 2 to 11 years, with an average duration of approximately 5 years. The decline is continuous but gradual. Central nervous system changes are accompanied by a gradual deterioration of the physical state of the patient, who becomes confined to his bed. Infections often occur, and intercurrent disease usually terminates the life of the patient.

Management. There is no known treatment for this disorder, and the therapeutic regimen must revolve around adequate supportive health and environmental measures.

The psychotherapeutic measures employed in this slowly progressive brain disease are of limited value because the flat affect common in Pick's disease serves to block the patient-doctor interaction so necessary for effective psychotherapy.

Alzheimer's disease

Definition. This form of progressive mental deterioration was described by Alois Alzheimer in 1906. It is often considered to be a presenile dementia, that is, a condition resulting from the early onset of an aging process or a pathological process usually encountered at advanced ages. Many pathologists believe that Alzheimer's disease and senile dementia are one and the same pathological entity. However, others support the evidence that Alzheimer's disease is and should be considered a specific entity unrelated to age.

Epidemiology. Although Alzheimer's disease may appear in the early sixties, when it is easily confused with senile brain disease, it occasionally begins in the 4th decade of life. It is found in approximately 4 per cent of patients who come to autopsy with mental deterioration. Apparently, it is the most common of the dementias occurring prior to age 60. The female-male incidence ratio is 3 to 2.

Etiology. Although Alzheimer's disease is not clearly a familial disorder, families in which a hereditary disposition exists have been reported in the liter-

ature. At the present time, the cause of this disease is unknown.

Pathology. Grossly, the brain shows a generalized atrophy. Superficially, the cortex appears similar to that seen in cases of senile dementia. Microscopically, the significant feature is the degeneration of nerve cells, with the appearance of neurofibrillary tangles arranged in the forms of whirls and baskets. In addition to this characteristic change, senile plaques are usually present.

Clinical description. As in many organic disorders, in Alzheimer's disease there is a gradual intellectual deterioration. But in spite of the loss of memory and the illogical reasoning, insight is often preserved. The awareness of impending insanity is a distressing complication in Alzheimer's disease. As neuronal destruction continues, speech becomes seriously disturbed, and involuntary movements of the arms and legs are frequently observed. Epileptic seizures can develop, and after each seizure a more rapid progress of mental deterioration is commonly observed. The course of the disease is progressively downward, with invariable fatal conclusion. The disease usually lasts between 2 and 5 years; the average is believed to be approximately 4 years. No specific treatment is known for this disorder. Only symptomatic and environmental support can be offered.

Differential diagnosis. Alzheimer's disease must be distinguished from Pick's disease, senile dementia, and cerebral vascular disease. The patient with Alzheimer's disease appears to be overactive, as compared with the loss of initiative seen in Pick's disease. Emotional distress and agitation are common in Alzheimer's disease. The distressing awareness of impending disaster is apparently not encountered in Pick's disease. The clinical and laboratory characteristics of the other major disorders—senile brain disease and cerebral vascular disease—that must be considered have already been discussed.

Prognosis. The usual duration of Alzheimer's disease is 2 to 5 years, although isolated cases have been reported to survive 15 years and more. Terminally, emaciation is severe, and the patient appears to be completely decorticated.

Management. The medical and psychiatric management is similar to that described for senile dementia and other chronic brain disorders. Marked restlessness occasionally requires the use of sedatives. This hyperactivity is a transient condition.

Disturbances of Metabolism, Growth, and Nutrition

Pellagra (niacin deficiency)

Definition. Pellagra is due to a vitamin deficiency of niacin (nicotinic acid) or its amide (niacinamide or nicotinamide). This disease is characterized by dermatitis, dementia, and diarrhea. Pellagra was first described in the 18th century in Spain and Italy; in 1735 a Spaniard, Gaspar Casal, named it *mal de la rosa*.

Frapolli recorded its occurrence in the peasants of Lombardy and labeled it *pelle agra* or rough skin. In 1866 the first case was recorded in the British Isles.

Epidemiology. In the last 10 to 15 years, the incidence of pellagra has decreased sharply in the United States. Prior to 1952, a large university clinic in the South saw between 20 and 30 patients with pellagra each year; in 1952, the number dropped to 4; between 1952 and 1959, 1 or 2 were diagnosed each year; and since 1959, not a single case has been recorded. Interestingly, the last patient to be observed had a psychotic reaction associated with pellagra.

The sharp decline in the incidence of pellagra is attributable to improved diet, especially from the addition of niacin and thiamine to bread. The actual use of niacin dates from 1927, when Joseph Goldberger introduced niacin for the treatment of pellagra. However, pellagra continues to occur in backward nations and is still encountered in chronic alcoholics, whose dietary intake of niacin is often seriously deficient.

Etiology. A deficiency of dietary niacin is a major factor contributing to the development of pellagra. However, in many instances, pellagra is apparently a multideficiency disease. For example, since the amino acid tryptophan serves as a precursor for nicotinic acid, tryptophan may be substituted in a diet that is deficient in niacin. Accordingly, many feel that in pellagra there must also be a deficient intake of tryptophan. There is evidence, too, that the neurological manifestations of pellagra are related to a deficiency in B vitamins other than nicotinic acid.

Pathology. Nicotinic acid is a coenzyme that is important in carbohydrate and probably in protein and porphyrin metabolism. Apparently, if changes are to occur within the central nervous system, a polyavitaminosis must be present, for a deficiency in nicotinic acid alone is of little consequence. The pathological changes that do occur in niacin deficiency are reversible until rather far advanced.

The earliest changes occur in the Betz cells of the motor cortex. The affected cells appear swollen and rounded, Nissl particles have disappeared, and the nuclei are eccentric. Similar cerebral changes are found in the smaller pyramidal cells of the cortex, the large cells of the basic ganglia, the cells within the cranial motor nuclei, and the dentate nuclei. In the anterior horns of the spinal cord, the lesions involve symmetrical degeneration of the dorsal columns and to a lesser extent the pyramidal tracts. Some pathologists believe that these changes are similar to those encountered in subacute combined degeneration. The cerebral changes within the brain in pellagra are similar to those encountered in Wernicke's syndrome, and it is probable that the two diseases have a common etiology.

Clinical description. Pellagra is characterized by a combination of symptoms involving the skin and the digestive and central nervous systems. The initial skin changes are a persistent erythema, followed by pigmentation of the skin resembling a severe sunburn.

Commonly involved are the backs of the hands and a bandlike area extending around the waist. In some cases the palms of the hands are also affected and, infrequently, the face, neck, elbows, knees, scrotum, or vulva. The mucous membranes in the mouth become inflamed, and a painful stomatitis results. The tongue develops a glazed bright red glossitis and frequently there develops angular fissuring of the tongue. Bloody diarrhea is frequent, with periods of diarrhea occasionally alternating with constipation.

Pellagra usually has an insidious psychic onset, and the first mental symptoms are usually regarded as psychoneurotic with depressive components. Early symptoms include weakness, anxiety, irritability, headaches, lack of energy, fatigability, dizziness, difficulty in concentration, and loss of recent memory. If the disease progresses, more serious psychiatric symptomatology becomes manifest. These severe mental symptoms may include stupor or clouding of consciousness, hallucinations, depression, delirium, catatonia, acute chronic brain syndromes, other schizophrenic-like behavior or anxiety, and manic or paranoid ideas. Organic brain symptoms, such as memory loss, disorientation, confabulation, and confusion, are also common. Evidence of central nervous system involvement includes tremors, convulsions, incontinence, cogwheel muscular rigidity or twitching, and irregular involuntary movements, such as uncontrollable sucking and grasping reflexes, spasticity, ataxia, and hyperreflexia.

Differential diagnosis. There are no pathognomonic mental symptoms that make it possible to distinguish pellagra from an anxiety state or schizophrenia without considering the other clinical features of the disease, particularly those that would indicate a niacin deficiency with its associated changes in the skin and digestive systems. Although pellagra is essentially an encephalopathy, the recognition of spinal cord involvement may contribute to the diagnosis.

Prognosis. Since pellagra responds readily to treatment, the prognosis is excellent, except in very advanced cases.

Management. It is essential that the patient be provided with adequate nutrition in the form of a balanced high caloric diet and supplementary vitamins (niacin, thiamin, and vitamin B complex). If the patient is unable to ingest food and supplementary vitamins, then nicotinic acid, niacin, or nicotinamide should be administered intramuscularly. Dietary niacin is found in yeast and many protein foods; fresh or canned salmon and some liver extracts are of particular value. Protein foods rich in tryptophan, such as milk, eggs, and wheat, are also helpful against pellagra. Mild cases of pellagra may be cured by giving 100 mg. of niacin every hour for 10 hours orally during the first 2 days. Most patients will improve rapidly within the first 48 hours. Even though supplementary vitamins are given, improvement may be slow and erratic if the patient is continued on a high

fat or carbohydrate diet, and a protein-rich diet is advisable.

In most cases of pellagra 500 mg. of nicotinic acid are usually administered daily by mouth in divided doses of 50 to 100 mg. After 2 weeks the dosage is reduced over a few days to a maintenance level of 25 mg. daily. Maintenance doses are especially advisable with elderly patients, where dietary control may be unreliable.

Pernicious anemia (vitamin B₁₂ deficiency)

Definition. Pernicious anemia is a chronic macrocytic megaloblastic anemia due to a vitamin B₁₂ deficiency. It is called a secondary deficiency disease because it is not usually due to a poor dietary intake of the vitamin but is the result of impaired absorption of vitamin B₁₂. This impairment is due to a permanent deficiency in Castle's intrinsic factor in gastric juice, which normally promotes the absorption of the vitamin B₁₂, extrinsic factor, from the intestines. Pernicious anemia may also be related to folic acid (pteroylglutamic acid), since the presence of this vitamin will cause the anemia to improve but will not prevent the subacute combined degeneration of the spinal cord that develops in most pernicious anemia patients and it may, in fact, aggravate the degeneration.

Clinical description. This disease usually occurs after the 5th decade. Its onset is frequently insidious, with a characteristic glossitis, gradually increasing weakness, paroxysmal abdominal pains, and other gastrointestinal complaints. There does not appear to be a clear temporal relationship between the development of symptoms referable to the nervous system and the apparent onset of the disease. Mental changes are of great significance; it is possible that a high incidence of mental symptoms accompanies this disorder, but it is difficult to know whether the psychic changes are due to organic pathology or represent a reaction to disability and discomfort. Although no characteristic symptom complex accompanies this disease, frequently encountered symptoms are irritability, memory defects, hallucinations, disorientation, and depression.

Management. Although pernicious anemia responds to the liberal use of liver extract, vitamin B₁₂ has replaced liver extract as the treatment of choice. Usually vitamin B₁₂ is given in daily doses of 50 to 100 µg. intramuscularly for a period of 2 weeks. Somewhat increased doses are recommended if there is neurological involvement. If larger doses are injected, a high percentage of the administered vitamin B₁₂ will be excreted. After the initial 2-week treatment period, the patient is placed on a maintenance dose of a minimum of 60 µg. of vitamin B₁₂ intramuscularly every 4 weeks. If the patient is seriously ill with a severe deficiency of vitamin B₁₂, larger intramuscular doses appear to be retained by the body. As much as 5,000 µg. have been given over a short period of time, but the value of this procedure is questionable. Folic acid

may be beneficial for the anemia, but it may be dangerous, since it occasionally aggravates the neurological manifestations of pernicious anemia. For this reason, many multiple vitamin preparations do not contain folic acid.

The diversity of mental symptoms preclude a routine psychotherapeutic approach. The usual delirious reactions should be treated symptomatically. It is necessary to maintain a stable, easily recognized environment and interpersonal relationships that are supporting and reassuring.

Beriberi (vitamin B₁ deficiency). A deficiency of vitamin B₁ or thiamine results in a disease characterized by psychological, neurological, cardiovascular, and gastrointestinal symptoms. When severe, the resulting disease is known as beriberi. The major psychological symptoms are irritability, fatigability, loss of appetite, sleep disturbances, and emotional lability. In severe cases, delirium may result. Neurological symptoms include a peripheral bilateral symmetrical neuropathy. In advanced cases, memory disturbance and external ophthalmoplegia of Wernicke's syndrome or encephalopathy may occur. Other symptoms of beriberi are disturbances of the pupillary response to light, cerebellar ataxia, and peripheral neuropathy.

Scurvy (vitamin C deficiency). Scurvy is a disease due to a deficiency of vitamin C and is characterized by hemorrhagic and bone abnormalities. Weakness, irritability, and depression are encountered. Treatment consists, in adults, of administration of 1,000 mg. of ascorbic acid daily in divided doses for 1 week; thereafter, 500 mg. are administered daily until all symptoms have disappeared.

Kwashiorkor (infantile pluricarcinial syndrome). This is a disease resulting from a severe protein malnutrition in childhood. Although kwashiorkor was first described in Africa, it is now known to occur in children in all underprivileged parts of the world. Psychiatrically, instability, apathy, and depression have been reported. The basic treatment is the administration of full cream milk by mouth.

Hypervitaminosis. This is a condition induced by excessive vitamin intake. The symptoms encountered in hypervitaminosis A and D include weakness, anorexia, anxiety, nervousness, and headache.

Hypothyroidism

Definition. Hypothyroidism, which is due to a deficiency in thyroid hormone, is designated as myxedema when it develops in an adult and as cretinism when it occurs in infants or children as a result of a congenital thyroid dysgenesis or a deficiency in early life of the thyroid hormone. In 1871, C. H. Fagge at Guy's Hospital first suggested that there was a relationship between a malfunctioning thyroid gland and cretinism. Three years later, Gull described myxedema and noted the resemblance of this adult disorder to that of cretinism.

Epidemiology. Cretinism has been a rare disorder in this country since iodized salt was introduced as a prophylactic measure. Although hypothyroidism in adults is a relatively common diagnosis today, progression to a state where the diagnosis of myxedema is justified is infrequent and declining. Adult myxedema occurs five times as often in females as it does in males. Its most frequent age of onset is between the ages of 30 and 60 years.

Etiology. This disorder is usually attributed to primary or secondary causes. Cretinism is usually considered a primary disorder, since it is due to a congenital absence or deficiency of thyroid hormone. Other primary etiologies are the destruction of the thyroid gland by disease or its removal surgically. Secondary hypothyroidism results from anterior pituitary gland failure.

Pathology. Deficiency of thyroid hormones has a widespread effect on the body. Since it affects the metabolic processes of the individual cells rather than any one system or particular organ, generalized changes can be seen in the skin, hair, heart, gastrointestinal tract, reproductive system, and central nervous system. One of the major functions of thyroid hormone appears to be the maintenance of excitability of nerve cells. Consequently, one finds cerebral manifestations as well as disturbances in the functioning of the cranial and peripheral nerves.

Clinical description. In hypothyroidism without myxedema, patients complain of easy fatigability, poor emotional control, vague aches and pains, menstrual disturbances, and anemia. It is evident that these symptoms are similar to many complaints associated with various psychoneurotic reactions. As hypothyroidism increases in severity, the patient's skin may become dry and brittle, with a loss of eyebrow and pubic hair. Cardiac changes include bradycardia and angina. Mental changes progress from mild mental dullness, apathy, drowsiness, memory defects, anxiety, and irritability to overt psychosis, "myxedematous madness." Although depressive and paranoid symptoms are very common, psychotic symptomology has no characteristic features and is apparently determined by the premorbid personality. Involvement of the cranial nerves, particularly the optic nerve, occurs, and central scotomata and other visual defects have been reported. Eighth nerve involvement may be present, as manifested by tinnitus, vertigo, hearing loss, and coordination difficulties.

Hypothyroidism of childhood or cretinism is commonly associated with mental retardation, delayed growth, dental abnormalities, a characteristic thick tongue and sharp, flat nose, widely spaced eyes, and a typically vacuous facial expression. The children are dwarfed and characteristically have a protuberant abdomen. The child's mental status may vary from dullness and apathy to euphoria. Many infants do not take on the characteristic cretinous appearance until the 2nd or 3rd month of life, when they have depleted

the supply of hormones transmitted in utero from the mother.

Differential diagnosis. Little difficulty should be experienced in the diagnosis of classical cretinism or myxedema. The inexperienced clinician may confuse a cretin with a mongoloid infant, but the mongoloid's characteristic eyes and facial features and his normal skin and hair texture readily distinguish him from the cretin. In adulthood, a patient with chronic nephritis may manifest mental changes quite similar to those seen in myxedema. Facial expression may be similar, but physical examination and laboratory findings should readily help in differentiating these disorders.

Prognosis. In cretinism there is a positive correlation between the degree of intelligence that can be attained and the speed with which thyroid therapy is started in the first few months of life. The prognosis is better in juvenile than in congenital cretinism. Adequate early treatment of cretins should cause a favorable response in all intellectual areas, and between 60 and 75 per cent attain normal intelligence. Unfortunately, this optimism in regard to restoration of normal mental functions as the result of the replacement of thyroid is not encountered in cretinous adults, where the prognosis is more guarded.

Management. The adult patient who has serious myxedema may return very slowly to normal if permanent changes in his psychic functioning have not occurred. In such individuals, the premorbid personality, particularly the psychic determinants that prevented the patient from obtaining adequate medical help, plays a role in the persistence of psychiatric problems. Accordingly, all patients diagnosed as myxedematous should receive psychiatric help.

A daily dose of 30 mg. of desiccated thyroid substance is the treatment of choice for all types of hypothyroidism, except cases due to specific iodine lack; then iodine therapy is instituted. It is usually recommended that therapy be started with a relatively small dose of thyroid, as sudden changes in the metabolic level of activity can have adverse effects on mental and cardiac functioning.

Hyperthyroidism

Definition. Hyperthyroidism or thyrotoxicosis is also known as Graves' or Basedow's disease. Robert James Graves, an Irish physician who lived during the first half of the 19th century, first described the characteristic symptoms of this syndrome and associated it with enlargement of the thyroid gland.

Caleb Hillier Parry, an English physician who died in 1822, was among the first to describe the symptoms that accompany exophthalmic goiter. Graves and Basedow, between 1835 and 1842, independently published articles describing this disorder in greater detail.

Epidemiology. Thyrotoxicosis appears to be common in cold climates and civilized societies. A low

incidence of hyperthyroidism is reported in Africa, China, and India. Professional and sedentary people are more frequently afflicted than are laborers. The disease is much more frequent in females than in males. In nongoitrous areas the ratio of incidence in females to males is approximately 4 to 1, but in endemic goitrous areas the ratio is lower. The disease usually appears after the 3rd decade of life and seems to be associated with other endocrine changes, such as pregnancy and the menopause.

Etiology. This disorder results from the excessive production of thyroid hormone. While hyperthyroidism is frequently associated with an increase in the size of the thyroid gland (goiter), some symptoms of the disease can occur with relatively little change in the size of the thyroid gland. True exophthalmic goiter is invariably associated with a diffuse enlargement of the thyroid gland. The actual enlargement and hyperplasia of the thyroid parenchyma are associated with and affected by changes within the central nervous system and the pituitary gland. The onset of this disorder is frequently associated with psychoendocrine changes and with a psychic trauma.

Pathology. In hyperthyroidism associated with exophthalmic goiter, the thyroid gland is bilaterally diffusely enlarged. Approximately three fourths of the patients with thyrotoxicosis show a diffuse type of hyperplasia; the remainder manifest nodular enlargements. Nodular hyperplasia is often termed "toxic adenoma." Typically, microscopic study of the enlarged thyroid gland reveals parenchymatous hypertrophy and hyperplasia. This microscopic picture provides cytological evidence of increased glandular secretory activity.

Clinical description. The clinical signs and symptoms of Graves' disease include goiter or enlargement of the thyroid gland, exophthalmos, fine tremors, restlessness, anxiety, irritability, increased perspiration, and emotional instability. Although anorexia occasionally occurs, there is usually no loss of appetite, but there is a progressive loss of weight and strength. An intolerance to heat develops, and the patient complains of cardiac palpitations, paroxysmal arrhythmias, and dyspnea. Other prominent psychiatric symptoms are hypersensitivity, suspiciousness, apathy, and depression. About 20 per cent of hyperthyroids may develop overtly psychotic symptoms. Most develop a manic excitement with schizophrenic-like symptoms—delusions and hallucinations. Less often, depressive psychotic symptoms and delirium are encountered.

Mental symptoms and changes are thus an important component of the clinical picture of thyrotoxicosis. As in other types of hormonal disturbances, it is difficult to establish the cause and effect relationship between the role of psychic conflict and the hormonal imbalance. The psychosomatic aspects of this disorder, particularly the role of psychic factors in its etiology, have been explored by a number of investi-

gators. Traumatic events were reported to precede the onset of the disease by several days to weeks. Other studies have confirmed that upward of 80 per cent of patients had severe emotional shocks preceding the onset of the illness. Many workers have reported that hyperthyroid patients were excessively dependent on a specific situation or person (a cardinal relationship). When the relationship was seriously threatened, hyperthyroidism was precipitated. Hyperthyroid patients are chronically anxious, and the anxiety is supposedly related to a fear of separation from a needed person. Such an individual may try to protect himself from loss of love by constantly giving to others and by displaying a pseudomaturity and independence. The affective state that most frequently accompanies hyperthyroidism is that of anxiety aggravated by depression. Some anxiety results from excessive thyroid hormone, but the exact role of anxiety both etiologically and symptomatically is controversial in hyperthyroidism.

Differential diagnosis. Anxiety states with accompanying tachycardia and weight loss may resemble thyrotoxicosis, and the differential diagnosis is often difficult. The vasomotor instability that accompanies anxiety is likely to result in a cold extremity rather than the warm extremity of hyperthyroidism, but this is an unreliable differential point. Determination of the basic metabolic rate is not only inaccurate but has been replaced by easier and more reliable methods, such as the determination of the serum level of protein-bound iodine or the establishment of the rate of radioactive iodine uptake following the oral administration of a tracer dose.

Prognosis. Symptoms are likely to recur in a successfully treated hyperthyroid, but the prognosis is improved when other modalities are used in addition to antithyroid drugs. Since it has been estimated that 50 per cent of hyperthyroid patients treated with thiourea drugs will have a relapse and recurrence of the disease within 1 year if the therapy is stopped, such patients must remain under constant medical surveillance. The prognosis is improved when other methods are used, such as radioactive iodine treatment. However, there is some controversy today about the most effective medical and surgical treatments of hyperthyroidism.

Management. Surgical therapy is the treatment of choice for most toxic nodular goiters. At least 75 per cent of patients with diffuse toxic goiters can be effectively treated with radioactive iodine, but this treatment is contraindicated in pregnancy and in nodular goiter. Other treatments used include thiourea drugs and surgical removal of the gland. Regardless of the therapeutic approach used, it is believed that most such patients benefit from psychotherapy. During critical phases of the disease, supportive psychotherapy is advisable. Insight therapy is employed when the thyrotoxic component of the illness is under reasonable control. Psychotherapy in the

management of hyperthyroidism is not a primary treatment—which should be medical or surgical—but is a valuable adjuvant therapy.

Hypoglycemia

Definition. Hypoglycemia is a state in which there is an abnormally low concentration of glucose in the blood. It may be cryptogenic or without demonstrable cause, or it can be symptomatic and therefore attributable to a number of disorders. Cryptogenic, spontaneous, or idiopathic hypoglycemia, although a relatively rare phenomenon, is of considerable importance to psychiatry.

Etiology. Symptomatic hypoglycemia may be due to an increase in insulin production by the β cells of Langerhans' islands. Such overproduction of insulin may be functional in 70 per cent of the cases, but it may also be due to a tumor of the pancreas or to insulin-producing neoplasms in other locations within the body. Hypoglycemia may also accompany the adrenocortical and adrenohypophyseal insufficiency that may occur in chronic liver disease, and it is occasionally found in encephalitis.

Pathology. The neurons of the central nervous system of man are markedly dependent on oxygen and glucose. Hypoglycemia quickly produces changes within the brain. If the glucose supply is not restored, the results are often serious. The effects of hypoglycemia, like those of anoxia, find the gray matter much more vulnerable than the white matter.

Clinical description. The early symptoms of hypoglycemia are similar to those produced by excessive epinephrine or in an anxiety state. The patient complains of flushes, sweating, tremors, headache, dizziness, nausea, weakness, and syncope. With prolonged hypoglycemia, sensory changes take place, such as numbness, tingling, and parasthesias in the extremities, tongue, and lips. Auditory and visual disturbances may develop, with illusions and hallucinations appearing. Diplopia and convulsions can occur, and changes of body image have been reported.

The effects of hypoglycemia on the brain seem to occur progressively, paralleling levels of brain function development; that is, the higher mental functions are affected first, and the more primitive and stable brain stem functions are the last to be involved.

Hypoglycemia must be considered when the patient reports episodes of extreme anxiety progressing to confusion and the development of focal neurological signs. Sometimes a periodicity relating to food intake is reported. At times, hypoglycemic episodes may closely resemble acute alcoholism. To complicate the problem further, hypoglycemic reactions may exist in some persons who apparently have a normal blood sugar and glucose tolerance test. It has not been established whether such individuals suffer from a faulty threshold mechanism or are for some reason unable to utilize the glucose available to them.

Differential diagnosis. Determination of fasting

blood sugar levels and glucose tolerance curves are of utmost importance. Those individuals suffering from cryptogenic hypoglycemic episodes have a hypoglycemic-like syndrome without significantly lowered blood sugar, and they present a fascinating and difficult clinical problem. The electroencephalogram may be of value, but it is affected in varying degrees from one subject to another. However, when changes are present, the restoration of glucose level by the ingestion or injection of dextrose leads to a prompt return to normal in the EEG; sometimes only a mild increase in blood glucose levels results in a rapid change in the EEG.

Treatment. When hypoglycemia is found to be symptomatic, it is evident that the underlying pathology must be the focus of treatment. When it is determined to be cryptogenic, efforts must be made to maintain the glucose level by multiple feedings and by avoidance of physical activity and stress situations. Treatment must be individualized and related to the frequency, severity, and duration of hypoglycemic episodes.

Diabetes mellitus

Definition. Diabetes mellitus is a chronic disorder resulting from a relative or absolute deficiency of insulin and a consequent disturbance in carbohydrate metabolism. Aretaeus, a famous Greek physician who lived in the 2nd century A.D., described and named the disease. Chinese medical writings as early as the 7th century mentioned the characteristic symptoms of polyphagia, polydipsia, and polyuria. Although many famous scientists were interested in this disorder, it was not until 1921 that Banting, Best, and Macleod developed a crude extract of insulin. Thereafter, other scientists eliminated the toxic substances from the extract and concentrated the active principal insulin.

Epidemiology. Diabetes mellitus is an increasingly prevalent disease, appearing most often in the middle and later years of life. The high incidence of diabetes among females represents a sex difference that does not become apparent until after the 4th decade. Occurrence varies in different races. It is very high in Jews and is infrequent among Chinese, Japanese, and East Indians. When it does occur, it is apparently mild in the latter group. It is frequently associated with obesity.

Etiology. The exact mechanism that underlies the development of diabetes has not been established. The three factors that appear to be related to diabetes are heredity, obesity, and a hormonal disturbance. The latter is much more complex than merely a deficiency of insulin. Experiments indicate that the pituitary gland and the adrenals play an etiological role in diabetes mellitus.

Clinical description. The development of the disease may be rapid, without obvious symptoms, or it may be insidious and remain undetected for a long period of time. It is common for the unsuspecting dia-

betic to seek medical assistance for the disturbing complications of the disease and for the metabolic disorder to be discovered during the examination. Complications that lead to detection include infection, pain, coldness of the extremities, and delayed healing after injury. Patients with well established diabetes mellitus complain of generalized weakness, increased thirst, frequent urination, and gradual loss of weight in spite of a good appetite. Pruritus is especially common and usually involves the genitalia. Impotence in the male and amenorrhea in the female are frequent presenting complaints of early diabetes. The degenerative changes are particularly disturbing, as they include generalized arteriosclerosis, early development of cataracts and retinitis, and serious infections.

A number of these symptoms and signs may be associated with or result from psychic conflict. Itching involving the genitalia and the decrease in sexual interest contribute to emotional complications. Obesity is probably the symptom most often related to psychological tension. The oral gratification derived from overeating as a substitute for affection and security often appears to be prominent in the premorbid personality makeup of the diabetic patient. In addition to this complex interaction of psyche and soma, it appears that a significant number of diabetics are pushed into the overt disease by a stressful situation. Psychoses caused by diabetes are rare, but when they do occur they are usually deliriums.

Differential diagnosis. Although the diagnosis of diabetes mellitus is occasionally suggested by the medical history, in most instances the discovery of glycosuria in a routine examination is the major factor in uncovering the disease. Glycosuria may be related to Cushing's syndrome and acromegaly and therefore must be differentiated from these conditions. Diabetic coma also presents a critical and difficult differential diagnostic problem, as glycosuria can accompany a cerebral vascular accident. It is also important to differentiate diabetic coma from a hypoglycemic reaction.

Management. Excessive anxiety and repeated exposure to stress complicate the management of this metabolic disorder. For example, the adult diabetic must resolve conflicts regarding the hereditary aspects of the disease, and the female diabetic must face increased risks in childbearing. For a parent of a juvenile diabetic, dietary restrictions and other limitations must be properly handled psychologically, so that the young patient will not feel abnormal or invalidated.

The treatment of diabetes mellitus includes controlling the patient's glucose and metabolism, maintaining general health, correcting nutritional abnormalities, educating the patient in self-care, and preventing and ameliorating the physical and psychological complications of the disease. In addition to diet, therapeutic measures include the use of regular

or modified insulin and the use of oral antidiabetic sulfonylurea compounds. Some juvenile diabetics use coma as a type of self-destruction; avoidance of this and other self-induced complications requires skillful psychological intervention.

Cushing's syndrome

Definition. Harvey Cushing in 1932 first published a description of the syndrome now known by his name. The clinical manifestations of Cushing's syndrome are caused by prolonged exposure to excess adrenocortical hormones. It is characterized by muscle wasting, obesity, osteoporosis, atrophy of the skin, and hypertension.

Epidemiology. Cushing's syndrome is a relatively rare disorder occurring in middle-aged people and somewhat more frequently in women than in men.

Etiology. This syndrome was originally associated with a basophilic adenoma of the pituitary gland. However, such tumors account for a very small proportion of individuals with this syndrome—less than 1 per cent of all pituitary tumors are of the basophilic type. It is now known that this syndrome has many causes, including exogenous steroids taken for therapeutic reasons. The most common causes include bilateral adrenocortical hyperplasia, adrenocortical adenoma and carcinoma, nonendocrine neoplasms (usually pulmonary in origin), adrenal rest tumors of the ovaries, and pituitary adrenocorticotrophic hormone-secreting tumors. These result in hyperfunctioning of the adrenal cortex and the excess production of adrenocortical hormones.

Pathology. In addition to the various types of primary pathology described above, the pathophysiology is important. Adrenocortical hormones influence many bodily functions and may result from an excessive secretion of pituitary adrenocorticotrophic hormones. Consequently, there are disturbances in electrolyte balance, carbohydrate and fat metabolism, protein regulation, and androgenic activity; the last results in virilism.

Clinical description. Patients with Cushing's syndrome have a characteristic appearance. There is an accumulation of adipose tissue, confined to the face, neck, and trunk, with the extremities being spared. Such patients are often described as having a buffalo appearance. In addition to this unusual fat distribution, there is an osteoporosis with dorsal kyphosis. It is not unusual to find purple striae over the abdomen, thighs, and upper arms. These patients bruise easily, with poor wound healing and a weakness and wasting of muscles. Fatigue and complaints of pain in the adipose tissue are common. Women are usually amenorrheic, and the masculinizing effects of the hormones produce a deepening of the voice, hirsutism, growth of the clitoris, and acne. Males are usually impotent.

This disorder is traumatic to the individual's psychic balance. Adjustment to a new body image that is repulsive to the person and to others, the pathology in the patient's sexual organs and interests, and the

consequent sexual confusion result in enormous anxiety. The patient's embarrassment restricts his normal social contacts, and a reactive depression or even a psychosis may result. These patients are usually withdrawn, emotionally labile or unstable, apathetic, impulsive, paranoid, and depressed.

Differential diagnosis. The diagnosis is established by finding the aforementioned symptoms and signs plus excessive excretion of steroids in the basal state. Further differentiation requires an exhaustive study of the individual, considering all the possible etiologies previously defined.

Management. If this syndrome is due to exogenous steroids, it is best to reduce steroid intake to the smallest effective dose or, if possible, to substitute a different type of therapy. Although many manifestations of Cushing's syndrome are reversible, two serious ones—hirsutism and osteoporosis—usually persist, despite the withdrawal of steroids. Adrenalectomy occasionally intensifies an accompanying depressive reaction, and during the postoperative period the suicidal risk is increased. An electrolyte imbalance due to disturbance in aldosterone may also occur postoperatively and result in delirium.

This disease may produce a traumatic experience that permanently affects the personality of the patient, even after removal of the cause of the pathology. The patient must be helped to find new methods of obtaining affection and of maintaining self-esteem. Previously established intimate relationships are often destroyed by the inability of friends or relatives to adjust to the change in the patient, and new relationships may have to be sought.

Acromegaly and gigantism. These are growth disturbances due to hyperfunctioning of the pituitary eosinophilic cells governing bodily growth. Since gigantism occurs in childhood, before epiphyseal closure has already occurred, there is an overgrowth of terminal parts of the skeleton, such as hands, feet, and jaw. Psychiatric symptoms include headache, loss of libido, and depressive and paranoid symptoms. These patients are frequently homosexual.

Addison's disease (chronic adrenal cortical insufficiency). This is an insidious disease caused by adrenocortical hypofunction and characterized by weakness, loss of appetite, nausea, loss of weight, pigmentation of the skin and mucous membranes, hypotension, and poor hydration. Psychiatric symptoms encountered are fatigability, mental instability, anxiety, depression, delirium, and overt psychoses characterized by paranoid hallucinations. Most of these symptoms are reversible with steroid therapy.

Porphyrrias

Definition. Under this heading are included at least two types of metabolic disorders—congenital or erythropoietic porphyria and acute intermittent or hepatic porphyria. The latter disorder is of interest to medical historians, for British psychiatrists recently

advanced the view that this was the psychotic disturbance that affected King George III, the monarch who initiated the repressive policies that caused the American colonies to rebel and ultimately achieve independence.

Epidemiology. Acute intermittent porphyria is the more common disorder of the two general types. It is more frequent in females (60 per cent) than in males (40 per cent) and is transmitted as a Mendelian dominant trait, although it may be sporadic or solitary. Congenital porphyria is a rare condition, more common in males than in females, and is transmitted as a Mendelian recessive trait.

Etiology. Porphyria is the result of an inborn error of metabolism. Porphyrin compounds occupy an important role in metabolic processes and are found throughout the body. In the congenital type of porphyria, the abnormal production of porphyrins is believed to occur in the bone marrow. In the acute intermittent type, excessive amounts of porphobilin and uroporphyrin are apparently produced in the liver. In the congenital type, the central nervous system rarely shows direct effects of the disorder. However, in the hepatic type, the central nervous system is frequently involved, and the patient may manifest disturbances in any area of thought and behavior.

Clinical description. Acute intermittent porphyria can manifest various symptoms, signs, and complications. It is believed that the majority, if not all, of the clinical findings can be explained on the basis of a disruption in the functioning of the nervous system. Abdominal pain is the most common symptom encountered. This symptom is thought to be the result of an autonomic neuropathy leading to an imbalance in the autonomic innervation of the gastrointestinal tract and other viscera. Other manifestations include convulsions, skin pigmentation, and excretion of a dark brownish red urine. Mental disturbances and polyneuritis are also frequently encountered. The mental symptomatology covers a wide spectrum of behavioral disturbances. If possible, an attempt should be made to distinguish those mental reactions that are a psychological response to the disease from those that are metabolic in origin. Responses can vary from extreme excitement to catatonic-like reactions. Hallucinations accompany the episodes of confusion. The entire treatment plan is complicated by the fact that these patients respond adversely to certain drugs.

Differential diagnosis. The differential diagnostic process does not usually include that of the common psychiatric disorders. However, acute porphyria must occasionally be distinguished from the neurological syndrome of Guillain-Barré. Often there is an excretion of a dark brownish red urine that points to the proper diagnosis. Other laboratory procedures are useful for diagnosis and therapy. For example, serum sodium frequently falls during an acute attack. This is thought to result from hypothalamic involvement,

which produces a transient secretion of an antidiuretic hormone.

Prognosis. The threat to life is directly related to the severity of the neurological involvement. In severely disturbed patients, the mortality may reach 80 per cent; it falls below 20 per cent in those who have little central nervous system involvement.

Management. These patients are sensitive to certain drugs that can precipitate or aggravate an attack of the disease. Barbiturates should never be administered under any conditions. Other agents that may precipitate attacks include the sulfonamides, ergot preparations, chloroquine, and alcohol. Because of their autonomic blocking activity, the phenothiazines are of considerable value. In addition to this blocking activity, the tranquilizing effect of these drugs adds immeasurably to the management of the disease. A dose of 25 to 30 mg. of chlorpromazine intramuscularly or orally may be given three times a day. Doses may be increased to 100 mg. four times a day. Rauwolfia alkaloids have been used with some success, and meprobamate is a safe substitute for barbiturates.

There is no specific treatment for this metabolic disorder, and for this reason avoidance of precipitating agents and other precautionary measures is advised. The ingestion of alcohol should be avoided. Relatives of patients with hepatic porphyria should be studied to determine whether latent porphyria is present in them.

Uremia

Definition. Uremia results from the kidneys' inability to remove toxic substances from the blood. These toxic substances are primarily the end products of protein metabolism and their derivatives.

Etiology. The breakdown products of protein metabolism appear to be a major etiological factor in this syndrome, but a detailed understanding of the mechanism of the toxic actions of these products remains relatively obscure. Although a major factor is the accumulation of urea, it is not the only one. Other possibilities that have to be considered are creatinine, uric acid, and the accumulation of inorganic and organic acid, proteolytic enzymes, and several other substances. Contributing factors are hypocalcemia, dehydration, acidosis, and hyperkalemia.

Pathology. Numerous toxic substances accumulate and circulate in the blood supply throughout the body. Brain cells are relatively easily damaged and hence the importance of preventing accumulation of toxic substances. Early in the course of the disease, cortical neurons and astrocytes undergo irreversible changes. As the disease continues, perivascular areas of necrosis occur within the brain, and there is demyelination in the cerebral hemisphere.

Clinical description. Early in the course of this disease, the patient reports the feelings of apathy, fatigue, and anxiety, increased drowsiness, and an

inability to concentrate, retain newly acquired information, and make decisions. A dull headache is common. Unlike hypertensive headaches, they are not focalized but are vague and generalized. The central nervous system manifestations occasionally undergo remission, and for brief periods of time the patient may feel better, think more clearly, and perform adequately. As the uremic state worsens, the memory defect worsens from recent to remote areas, speech becomes slurred, and the patient's generalized muscular weakness interferes with coordination. Irritability is characteristic, and depressive paranoid features are rather frequent. Delirium may ensue, as may other overt psychoses. These mental changes and the cyclic course of the disease are of considerable importance in establishing testamentary capacity in older patients with uremia. Often the patient progresses through a confusional state to coma and finally death. Consistent with this picture, the patient may manifest focal neurological disturbances. Generalized seizures occur in the terminal stages.

Differential diagnosis. The two most common metabolic disorders that result in impairment of brain function are uremia and diabetes. Today it is rare that the existence of uremia is not known prior to the onset of mental symptoms. This is not the case in diabetes. Although seizures may accompany uremic coma, they may also continue after recovery from a uremic episode. In addition to focal brain changes that may produce epileptogenic foci, there is a persistence of generalized cortical irritation. Therefore, the recurrence of seizures is not an indication that the level of toxic substances in the blood stream has again increased.

Treatment. In recent years the use of external hemodialysis, the artificial kidney, has been very useful in preventing the development of uremia in many patients, even though the long term prognosis is guarded when dialysis is used. Reports indicate that, in some instances, external hemodialysis can produce a reversal of mental and neurological abnormalities. However, in continued dialysis over a prolonged period of time, depression is often encountered. Otherwise, treatment is based on the medical or surgical management of the underlying kidney pathology and the proper handling of the emotional reaction to a severe life-threatening disease.

Suggested Cross References

See Solomon's Chapter 10 on neurology for further discussion of the senile and presenile brain diseases. Paranoid ideation and depression, which commonly form a part of the clinical picture of these conditions, are discussed in greater detail in Chapter 17 on the affective reactions, in Section 16.1 on paranoid reactions, and in Section 24.2 on the neurotic depressive reactions. Milieu therapy, which constitutes a

major management modality in these conditions, is further discussed in Chapter 36.

Various hormonal disorders are covered in Cleghorn and McClure's section on the psychosomatic aspects of endocrine disease (Section 30.9). For information regarding the biochemical processes associated with hypoglycemia, see Section 2.2 on neurochemistry in Area B, on the basic behavioral sciences. For a more detailed discussion of cretinism, see Cytryn and Lourie's chapter on mental retardation (Chapter 22). Subacute combined degeneration and its relationship to pernicious anemia are covered in Waggoner's section on brain syndromes associated with diseases of unknown cause (Section 19.3).

19.3 BRAIN SYNDROMES ASSOCIATED WITH DISEASES OF UNKNOWN CAUSE

RAYMOND W. WAGGONER, M.D.,
Sc.D.

Paralysis Agitans

Although paralysis agitans, as first described by Parkinson nearly 150 years ago, afflicted people in the senile or presenile period, the term has since come to include conditions with comparable symptoms caused by processes other than senility and vascular disease. As originally described, it was a degenerative extrapyramidal system disease involving primarily the basal ganglia. Since the original description—especially since the recognition of various other causes, such as encephalitis—the syndrome has been classified as idiopathic, postencephalitic, vascular, or toxic.

Etiology. The cause of the idiopathic variety, as the name implies, is unknown. Some cases develop years after the patient has had an encephalitis. Certain encephalitic epidemics seem to result in more postencephalitic paralysis agitans cases than others. This was true of the epidemic occurring after World War I. The condition may also result from certain intoxications, such as carbon monoxide.

Pathology. Although the pathology is primarily in the basal ganglia affecting the substantia nigra, the lenticular nucleus, and the caudate, pathological changes have been found in other parts of the central nervous system as well. Some authors consider the substantia nigra to be most seriously affected in postencephalitic cases.

Clinical description. The symptoms are primarily extrapyramidal. They develop gradually and are usually characterized by tremor, slowness in movement, and fatigue. There is also an increase in muscle tone of the type described as rigidity, which results in a characteristic body posture and facial expression, the latter being described as a masked facies, with absence of blinking. The tremor is coarse, involving primarily the upper extremities and may be seen best in the hands. It may be unilateral or bilateral, and the characteristic movement of the thumb and fingers is described as "pill rolling." The tremor and to a certain extent the rigidity may disappear in reaction to a sudden stimulus.

There is marked slowing of movement except for the momentary reaction to an exciting stimulus. Movement of an extremity by the examiner may result in a kind of jerky resistance described as the cogwheel sign. Frequently, there is an involuntary tendency to increase the speed of gait (festination), the patient being able to stop only by coming against a solid object. The handwriting may be small, cramped, and quavering, and it is quite characteristic.

Some authors, such as Diller and Riklan, think that there is no parkinsonian type of personality but do suggest that a large percentage of patients come from broken homes and describe their childhood as having been unhappy. In Diller and Riklan's series, 59 per cent were considered to have been normal or neurotic, 14 per cent to have had mental deterioration, and 5 per cent to have been schizophrenic.

Mitscherlich, in a series of 40 patients, noted that such patients had in common a compulsive, neurotic character with closely associated aggressive impulses. Other authors have observed that some paralysis agitans patients are driving and reckless, have assertive personalities, and do not respond favorably to medical therapy.

Most authors think that significant mental symptoms in patients with paralysis agitans are not usual. In general, such patients appear to have their symptoms coincidentally with the extrapyramidal disease rather than as a result of or in association with it. The following case is illustrative of this point of view.

A 48-year-old white female had a history of paralysis agitans symptoms, beginning approximately at the age of 45. There was no history of a preceding encephalitis, even though the onset of symptoms in this instance was somewhat earlier than might be expected in the idiopathic type. At about age 25, the woman had severe phobias and obsessional thinking. By the time of the onset of the Parkinson syndrome, the phobic and obsessional reactions were being manifested as delusions and were associated with a severe depression. The patient had been the aggressive member of the family, taking almost the entire responsibility for the children and even for her husband's business. The severe depressive reaction, with much suicidal preoccupation, was apparently concerned primarily with her basic anxiety and her awareness of the inevitable progression of her disease.

In this patient, the psychiatric symptoms preceded by several years the onset of the paralysis agitans, and the two conditions were actually coincidental.

If a sufficiently careful history is taken, it will almost inevitably be determined that there is not a significant relationship between mental symptoms and paralysis agitans other than those associated with anxiety and depression. The exceptions are those instances where the symptoms are the result of generalized cerebral disease, as in encephalitis or with vascular changes.

Differential diagnosis. The differential diagnosis is usually not particularly difficult, although early in the disease hereditary familial tremor may be confused with paralysis agitans.

Prognosis. The prognosis in paralysis agitans is one of inevitable progression over a number of years. Death usually results from an intercurrent infection or coincidental disease. Some of the mental symptoms may result from an awareness of the inevitable progression of the disease.

Treatment. Treatment of paralysis agitans is palliative only. Adequate rest is of vital importance. Drugs with parasympatholytic action are most effective. There are several synthetic drugs of this type, such as trihexyphenidyl (Artane) and benztropine methanesulfonate (Cogentin). Antispasmodics, such as procyclidine (Kemadrin) and cyerimine (Pagitane), may be of value. It is often necessary to try several drugs or combinations before the best treatment for the individual patient is found.

Surgical procedures have been reported to be of great value in selected cases. Psychiatric symptoms associated with paralysis agitans should be treated in accordance with the type of symptom manifested. Thus, paranoid reactions may be controlled in some cases by the use of phenothiazines such as Stelazine, but care must be exercised not to exaggerate the muscular disability. In depressive reactions, antidepressant drugs such as imipramine (Tofranil) or desipramine (Norpramin) may be useful. The author has found that the monamine oxidase inhibitors are at times of value. Appropriate precautions in the use of such drugs should always be observed.

Subacute Combined Sclerosis

The condition described as subacute combined sclerosis or posterolateral sclerosis occurs most commonly in association with pernicious anemia. It may also be seen in various toxic states and in conjunction with or as a result of various infectious diseases causing some disturbance in the nutritional state of the individual. Since it may occur in association with so many different types of difficulty, the symptoms are likewise extremely variable.

Pathology. The pathological changes are primarily in the spinal cord and consist of degeneration of the posterior and lateral columns of the spinal cord. There is loss of myelin with some reparative gliosis.

Clinical description. It is characterized in general by subjective and, at times, objective sensory changes and by motor symptoms. The sensory symptoms are primarily those of various types of paresthesias. The motor symptoms are associated with varying degrees of incoordination, muscle weakness, and fatigue and by variable manifestations of pyramidal tract involvement, such as spasticity, increased reflexes, and abnormal reflexes, such as Babinski's sign. There is loss of vibratory and position sense in the lower extremities and a positive Romberg's sign.

Pernicious anemia is defined as a chronic macrocytic hyperchromic anemia with megaloblastic hyperplasia of the bone marrow. It is inevitably associated with absence of hydrochloric acid in the gastric con-

tents. This finding may be present for many years before the onset of symptoms. The laboratory and clinical manifestations are assumed to be the result of the reduced ability of the individual to absorb vitamin B₁₂ from the gastrointestinal tract secondary to failure of the gastric mucosa to secrete the intrinsic factor. Pernicious anemia occurs most often in the white race and after the 5th decade of life.

Patients with severe anemia may have transient mental changes, consisting of irritability, memory defects, hallucinatory manifestations, and even disorientation. If the diagnosis is made early and treatment promptly instituted, such symptoms tend to disappear when the blood count is restored to normal.

Lewin suggested that depression may be a common denominator in the etiology of pernicious anemia by "reducing the intrinsic factor below the critical level required for normal erythropoiesis," and he concluded that a genetic factor leaves certain people prone to such events. Wiener and Hope have pointed out that pernicious anemia is associated with a subacute degeneration of the brain that is essentially the same as the more familiar subacute degeneration of the spinal cord, and noted that there is nothing consistently characteristic about the resultant mental symptoms. They pointed out that the various behavioral disorders may appear years before the anemia is diagnosed. Numerous reports in the literature indicate varying degrees and types of mental symptoms from mild states of depression to actual psychosis. Wiener and Hope emphasized that those patients with neurological and psychiatric manifestations require a greater amount of therapy than is required to maintain a normal blood picture.

It is vitally important that the diagnosis of pernicious anemia as a possible factor in the patient's mental symptoms be determined early, since the degenerative changes associated with this condition can be prevented by early and active therapy but, once established, usually persist.

Behavioral changes are often seen as the earliest sign of the disease. The following case illustrates this sort of reaction.

The patient, a 55-year-old white housewife, had a history of almost chronic depression but with marked exaggeration in episodes occurring over a period of 18 years. The patient believed that the original depression was precipitated by a hysterectomy. Because her mother had had pernicious anemia, a gastric analysis was done at the time of the hysterectomy, and a histamine-fast achlorhydria was found. However, no treatment for the potential pernicious anemia was given, since the blood picture, with the exception of a low white count, was considered to be within normal limits. Over a period of years, the patient was in a number of hospitals with varying treatments for her depression, including shock therapy.

During the course of evaluation for the fifth acute episode of depression, the history of the achlorhydria found 18 years previously was noted. A gastric analysis demonstrated the continuation of this finding and blood changes that were suggestive of pernicious anemia. The patient's blood picture returned to normal with the injection of 100 µg. of vitamin B₁₂ every week for 2 weeks, followed by 100 µg. every 3

weeks. However, the depression, complicated by a number of phobias, continued, and so the vitamin B₁₂ injections were increased to twice weekly, with considerable improvement of the depression but with continuing anxiety, which was controlled by a mild tranquilizer medication.

Differential diagnosis. In the differential diagnosis, it must be remembered that endocrine dysfunction, various infectious diseases, and nutritional and toxic conditions may be associated with posterolateral sclerosis. Similar clinical neurological pictures may be found in multiple sclerosis, primary lateral sclerosis, and various other spinal cord syndromes. Since the most common source of such cord changes (subacute combined sclerosis) is pernicious anemia, it must be carefully looked for in the diagnostic studies.

Treatment. In those patients where the diagnosis of pernicious anemia can be established, vitamin B₁₂ injections should be used, generally in much larger doses than are ordinarily used for pernicious anemia without neurological or psychiatric symptoms. A dosage of 50 µg. intramuscularly every other day until remission of symptoms occurs is recommended. Folic acid is contraindicated since it may aggravate the neurological lesions. Vitamin B₁₂ can be used in conjunction with antidepressant drugs in those patients who have a significant degree of depression. Symptoms such as irritability and memory defects, tend to disappear soon after the beginning of adequate treatment for the anemia. If such symptoms persist, they should be treated as comparable symptoms in a chronic brain syndrome.

The prognosis is somewhat variable, dependent on the source of symptoms and time of diagnosis. Similarly, treatment is dependent on the source of symptoms, with good results frequent when treatment is instituted early.

Systemic Lupus Erythematosus

Systemic lupus erythematosus is a disease condition characterized by skin eruption, prolonged fever, visceral lesions, and other constitutional symptoms. The severity of the condition may vary considerably from that of a very mild involvement to a severe and fulminating type of condition. Patients with this condition may have involvement of any part of the nervous system, accompanied by severe neurological or psychiatric disturbances. Clark and Bailey pointed out that these symptoms may be of the utmost variation and may be misinterpreted, leading to a mistaken diagnosis.

Clinical description. The disease is found most commonly in young women but may affect persons of either sex and at almost any age. Its course may vary from acute to subacute to chronic. Occasionally the serological reaction for syphilis may be falsely positive. The condition may involve almost any organ of the body and is associated with a leukopenia and a positive lupus erythematosus blood clot test. Lupus erythematosus cells may be found in the sternal mar-

row. The disease is an inflammatory process involving connective tissue and smaller blood vessels. The clinical picture varies with the acuteness of the disease and the organ involved.

In Clark and Bailey's series of 100 cases, psychiatric phenomena were found in 17 patients. Seven had anxiety with personality changes and memory defects, 3 showed emotional lability, and there was mental deterioration in 2, depression in 2, obsessive trends in 1, paranoid reaction in 1, and hallucinations with fever in 1.

In another series of 40 patients reported by O'Connor, 22 patients had psychotic episodes during one or more hospitalizations, four had neurotic symptomatology, and only 14 had no significant psychiatric symptoms. O'Connor feels that those patients who became psychotic had a more severe form of systemic lupus erythematosus and that a larger amount of steroid, nearly twice as much, was necessary to control the symptoms than in the nonpsychotic patients. He also concluded that the presence of a psychosis is not a good reason for the complete and immediate withdrawal of steroid therapy.

McClary et al., after studying 14 patients, feel that there is a predominance of obsessional features in the personality patterns of patients with disseminated lupus erythematosus. Since the condition results in a restriction of physical activity, this becomes a severe threat to those persons who have made use of activity as a means of relieving anxiety and depression. They raised the possibility that the emotional tensions generated in personal conflicts may contribute to the tissue pathology of the disease. O'Connor pointed out that psychotic reactions in this disease were described before the advent of hormonal therapy. Since both neurotic and psychotic reactions occur during the use of cortisone and adrenocorticotrophic hormone and since these are used in the treatment of lupus erythematosus, some correlation might be expected. Cortisone, he said, may be a potentiating factor in the development of the psychosis rather than the cause. He differentiates between an acute brain syndrome with delirium and a schizophrenic-like reaction. He believes that more than one factor is responsible for the psychiatric disturbances seen in systemic lupus erythematosus. The possible factors are diffuse organic brain damage, large doses of steroids, and psychological factors, such as a previous personality disorder or acute emotional trauma. All these factors must be considered in order to manage the individual patient appropriately.

Astimofeev, in reporting on 18 patients with systemic lupus, states that all had psychic disturbances. These were described as delirium, hypnotic hallucinations, anesthetic manifestations, and psychotic symptoms of an organic nature with epileptiform seizures, memory disorders, and dementia. There was some discussion of the effect of hormone preparations on the psychiatric symptoms.

Messel and Sullivan have reviewed the literature of the past 60 years concerning the association between psychosis and systemic lupus erythematosus and reported that 227 cases of this association were found. The average incidence of psychosis in the cases reviewed was about 22 per cent. The psychiatric manifestations are variable and may be associated with a neurological disorder. The behavioral disorders, including psychosis, may antedate by many years the other features of the disease and psychosis due to the disease may respond to steroid therapy.

Differential diagnosis. This condition is of particular importance in the differential diagnosis from functional psychosis. The psychiatric symptoms demonstrated by patients with systemic lupus erythematosus should be considered as manifestations of an organic brain syndrome, acute or chronic, as demonstrated by the history of the individual case.

Prognosis. The process may run a very acute course, with death occurring in a few weeks or months, or there may be remissions, with the disease lasting several years. The prognosis must be considered serious.

Treatment. The treatment of systemic lupus erythematosus is primarily by the use of steroids. Some authors recommend a decrease in the amount of steroid therapy if psychiatric symptoms develop. Other authors feel that the dosage should be increased under such circumstances. There is fairly general agreement that steroid therapy should not be discontinued if psychiatric symptoms appear. The physician's judgment concerning the individual patient must be exercised in such instances. Phenothiazines may be used in conjunction with steroid therapy. The types of phenothiazines used should be correlated with the kind of psychiatric symptom complex. Thus, in those with paranoid or hallucinatory manifestations, the more potent phenothiazines are apt to be more useful; antidepressant drugs should be tried for those patients with depression as the significant psychiatric symptom.

Wilson's Disease

Wilson's disease or hepatolenticular degeneration is a disease entity with characteristic clinical and neuropathological features.

Pathology. The pathology consists of atrophy of the lenticular nuclei with loss of cells and with glial overgrowth. Associated with these changes is a disturbance of liver function, usually a cirrhosis. One case has been reported of fracture of the liver, followed by fairly characteristic symptomatology of Wilson's disease. At autopsy, loss of cellular formation and overgrowth of glia in the lenticular nuclei were found.

Clinical description. The disease is characterized by a chronic, progressive course, with a rigid type of hypertonicity, involuntary movements, and mental

disturbances. It generally occurs in the 3rd to 5th decade and is associated with liver sclerosis and with degeneration, primarily of the lenticular nucleus but with occasional involvement of the caudate nucleus as well. There is a general disturbance of protein metabolism, primarily involved with the inability to bind serum copper.

Usually, the onset is gradual, with a tremor not unlike that of paralysis agitans and hypertonia also similar to that of paralysis agitans. In the characteristic case, there is a Kayser-Fleischer ring, a greenish brown ring in the cornea. In the majority of cases, some emotional disturbance occurs, and this varies considerably in degree and quality. In some cases the behavioral disturbance takes the form of loss of impulse control and, in other cases, emotional lability. There is a characteristic organic brain syndrome of the chronic type associated with suspiciousness, impairment of memory and judgment, and progressive mental deterioration. In some instances, psychosis with delusions and hallucinatory manifestations may occur.

Knehr and Bearn reported a study undertaken to examine the nature and extent of psychological impairment in seven patients with Wilson's disease. There was loss of capacity for conceptual thinking in all cases, a lowered flicker frequency threshold, and prolonged after-image. On the other hand, the accuracy of simple pattern perception and size of visual span of attention was similar to that found in normal subjects.

Etiology. There is much discussion in the literature about the pathogenesis of the condition. A number of theories have been advanced: (1) that the primary disease occurs in certain areas of the brain, which results in disease of the liver; (2) that the findings of pathology in both brain and liver are expressions of an heredodegenerative process; (3) that an underlying metabolic difficulty is responsible for changes in both organs; (4) that changes in the brain are produced by disease of the liver; and, more recently, (5) that disturbances in copper metabolism are primarily the source of the difficulty. Reports in the literature indicate that factors of the last three hypotheses may all be involved in the etiology of this difficulty.

Differential diagnosis. In the differential diagnosis, multiple sclerosis may be considered, but the type of tremor and hypertonicity are quite different. Paralysis agitans may present a quite similar clinical picture, and the differential diagnosis may be quite difficult. The most characteristic difference is the Kayser-Fleischer ring.

Pseudosclerosis (Strümpell-Westphal disease) is considered by some to be in the same category as Wilson's disease. Others consider it to be a separate entity. The clinical and neuropathological findings are essentially the same, and it does not seem to be important to make a differential diagnosis. These

cases also demonstrate significant mental disturbance with restlessness, emotional instability, and progressive mental deterioration.

Progressive pallidal degeneration (Hallervorden syndrome) is a somewhat similar condition associated with degeneration of the pallidum and with degenerative changes in the striate body and in the cerebrum. The condition occurs in childhood or adolescence, and the course may run for several years. There is an associated rigidity, difficulty in speech, and the development of involuntary movement. In all such cases there is reported progressive dementia. Premortem diagnosis is difficult.

Prognosis. The prognosis is not good, since the disease is progressive.

Treatment. Recently, chelating agents have been used with some possible benefit. In cases that manifest suspiciousness or paranoid symptomatology, particularly if there is a tendency to act on such ideas, the more potent phenothiazines may be used; the muscle symptoms under such circumstances may be exaggerated.

Friedreich's Ataxia

Friedreich's ataxia or hereditary spinal ataxia is a condition that occurs fairly early in life, usually beginning in the first or second decade. It is characterized by the gradual development of ataxia, until walking and eventually even standing and sitting become impossible.

Etiology. The cause of the disease is not known, but it is generally considered to be both inherited and familial, although it may appear sporadically. The transmission of the disease is frequently through the mother. The symptoms often appear to have been precipitated by infection.

Pathology. The neuropathological changes are found primarily in the spinal cord, although some changes may be found in the cerebellum. Some degeneration of the pyramidal tracts may occur, but the more marked changes are found in the posterior column and the spinocerebellar tracts.

Clinical description. The signs and symptoms, as indicated by the name, are primarily those of ataxia with loss of position sense. Muscle irritability may be noted. Nystagmus is almost always present. Tendon reflexes in the lower extremity are usually lost early, but late in the disease evidence of pyramidal tract disease may be found.

Since the disease affects primarily the posterior and lateral columns, both sensory and motor changes are noted. The sensory changes are manifested primarily by loss of position and vibration sense; tactile, pain, and temperature senses are usually normal. The condition is associated frequently with pes cavus, and in many cases there are changes in the spine.

In most instances there are other neural and extra-neural abnormalities. In families in which the disease occurs, members of the family who do not have

symptoms of the disease may be found to have various other abnormalities. Malformations or somatic anomalies may be present almost anywhere in the body. The condition commonly occurs in individuals who are mentally retarded; focal changes have been reported. Various kinds of mental disturbance have been reported, including paranoid delusions, outbursts of excitement, and depressive and confusional states. The condition runs a slow, progressive course; Lowenberg and Waggoner reported the case of a patient who was first seen in 1916 and who died 14 years later.

Differential diagnosis. The differential diagnosis is not difficult except from heredocerebellar ataxia, which usually manifests itself later in life. The presence of nystagmus, speech disturbance, ataxia with evidence of posterior and lateral column involvement is characteristic of Friedreich's ataxia.

Prognosis and treatment. The disease is a slow, progressive one, with inevitable complete incapacity. There is no treatment for the disease other than the control of aberrant behavior by the use of psychotropic drugs.

Diffuse Cerebral Sclerosis

Diffuse cerebral sclerosis is a term used to describe a large number of degenerative conditions characterized by widespread subcortical demyelination, usually associated with some neuronal degeneration and glial proliferation. Although rare, Schilder's disease is the most common of a number of similar types, which include Pelizaeus-Merzbacher disease.

Pathology. The neuropathology of diffuse sclerosis is characterized by discrete and confluent areas of demyelination, somewhat similar to the findings of multiple sclerosis. Gliosis develops as the disease progresses.

Clinical description. Schilder's disease occurs primarily in infants, adolescents, and young adults. The disease can begin without warning and is manifested early, primarily by mental changes and by visual disturbances. There is a decline of intellectual capability, accompanied by character changes. The child may become apathetic and confused within a few weeks; there is often evidence of pyramidal tract disturbance. The onset may be either acute or insidious, with the occurrence of symptoms of various sorts, but characteristically the picture is one of a chronic organic brain syndrome, which may be complicated by the occurrence of convulsive attacks and visual disturbances.

Differential diagnosis. It may be difficult to differentiate this condition from encephalitis and perhaps even brain tumor. However, there is no clinical evidence of infection, as is frequently seen in encephalitis, nor is there evidence of increased intracranial pressure, as in brain tumor. There are more mental changes than occur in multiple sclerosis.

Pelizaeus-Merzbacher disease is an unusual form of diffuse sclerosis. There seems to be a strong heredo-familial trend in this disease. It is characterized by a combination of cerebellar and cerebral symptoms. The symptoms are manifest early in life, but it is a slow, progressive disease, usually lasting for a number of years. The mental changes are those characteristic of an organic brain disease associated with mental deterioration. Although this disease may be confused with Schilder's disease, the course of the disease is quite different—that of Schilder's disease being much more rapid. The mental symptoms of both Schilder's disease and other forms of diffuse sclerosis are not characteristically diagnostic.

Prognosis and treatment. The prognosis is bad, and there is no known treatment. However, aberrant or hyperactive behavior should be controlled by the use of psychotropic drugs.

Huntington's Chorea

In 1872, Huntington described a hereditary disease associated with progressive degeneration of the basal ganglia and cerebral cortex and characterized by choreiform hyperkinesia and a chronic progressive mental deterioration. The initial symptoms usually appear between 35 and 50 years of age. It is commonly an inherited familial disease. It involves both Caucasian and Negroid races. The disease is without known etiology.

Pathology. Neuropathological changes are found primarily in the striatum, neostriatum, and cerebral cortex. Neuronal degeneration is followed by gliosis.

Clinical description. Its onset is insidious, with restlessness, clumsiness, purposeless involuntary movements, and serious mental changes. These symptoms are followed by facial grimacing and involuntary choreic movements of the fingers. Difficulty in speech occurs early, and in severe cases there are choreic movements of the tongue, lips, palate, larynx, and diaphragm. Muscular hypertonicity occurs, with grotesque postural attitudes.

There is no difference with regard to sex involvement, and occasionally cases occur without definitive family history. Once the disease has developed in a family, it tends to continue from one generation to another. As many as half of the members of the family may develop the disease. As has been pointed out, the disease is degenerative in character.

Mental symptoms occur in all cases and are those of a progressive, chronic, organic brain syndrome, characterized by indifference, apathy, impaired comprehension, and loss of memory. There may be associated periods of irritability and of impulsive behavior. In some instances the patient may develop characteristic paranoid ideation, and there may also be evidence of anxiety reaction and contrasting euphoria and depression.

Prognosis and treatment. The disease is progressive, inexorable, and incurable. Treatment is of

no significant value, although the phenothiazines seem to give some relief for the muscular hyperactivity.

Myasthenia Gravis

Myasthenia gravis is a condition characterized by excessive fatigability of the voluntary muscular system. There is marked weakness or temporary paralysis of muscle groups after exercise. Those muscles innervated by the bulbar nuclei are usually the first and most seriously involved. Some involvement of involuntary and smooth muscles has also been reported. The actual cause of the condition is not known, although numerous factors have been blamed—the most common one being an involvement of the thymus gland.

Clinical description. The picture of mild curare poisoning is clinically similar to that of myasthenia gravis, and myasthenic muscles respond to a much greater degree to curare than normal muscles. The age of onset is usually in the 2nd to 4th decade, and it is said to occur more commonly in females than in males. The most common presenting symptoms are disturbance of extraocular movement and drooping of the eyelids. The symptoms become more marked on exercise and are relieved by rest.

The disease is usually slowly progressive but may not be so in all cases. Mental symptoms are not of the organic brain syndrome type but, rather, are those of a reactive depression secondary to the presence of the symptomatology of the disease or of anxiety.

Prognosis and treatment. The prognosis of the disease is fair, with considerable relief from the symptoms by the use of a cholinesterase inhibitor such as pyridostigmin bromide (Mestinon). Antidepressants may be used with caution if indicated by the patient's condition. In these patients the amphetamines should be used only with extreme caution. Anxiety, when present, is best treated by the less potent phenothiazines such as chlorpromazine (Thorazine), rather than by such tranquilizers as chlordiazepoxide (Librium), diazepam (Valium), or meprobamate, which may increase the muscle disability.

Periodic Psychoses Associated with Peculiarities of Water Metabolism

These are unusual conditions in which a marked increase in the intake and output of water is associated with the development of an acute brain syndrome. The author has seen two such cases in which, apparently as the result of an emotional disturbance, both patients markedly increased their water intake and subsequently demonstrated disturbances in attention and concentration, confusion, disorientation, and delusional and hallucinatory manifestations. The patients were both female. Hospitalization and control of fluid intake resulted in a disappearance of the symptoms within 3 and 4 days, respectively. One patient was seen during the fifth episode of acute psychotic reaction, the other patient during the

second episode. No other source of mental symptoms had been demonstrated by previous studies.

Lesokhina, in reporting on some peculiarities of water metabolism in periodic psychoses, described 27 women, the majority of whom had had more than five psychotic attacks with motor agitation. During the attacks the hydrophilic properties of the body tissues were increased as compared with normal and interattack figures. Posterior pituitary preparation (Pituitrin) given during the attack had no effect on the water output. In the apparently normal intervals, it produced the usual effect. Lesokhina suggested that the increased tissue avidity for water and the other associated somatic changes are manifestations of stress reaction to an unknown toxin. Such a reaction probably occurs in a response to a significant degree of emotional stress.

Treatment. In the treatment of such psychoses, the patient must be under careful medical supervision, which can be adequately done only in a hospital situation. The primary purpose of hospitalization is to limit the fluid intake for a sufficient length of time, so that the patient does not revert to this type of behavior when supervision is discontinued. Psychotherapy is of value for the underlying neurosis.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis is a disease involving the cells and pathways of the pyramidal tract from the cortex to and including the spinal cord. It generally manifests itself in the 4th and 5th decades, but it may occur at other ages. The cause of the condition is not known. It is primarily a disease of the spinal cord and is associated with progressive muscular atrophy. There is some suggestion that the condition may be familial or hereditary, but it is not generally considered in this category.

Etiology and pathology. A trauma has been considered a causative or precipitating factor by Hassin and others. Waggoner and Lowenberg, however, do not believe that trauma is significant etiologically. They reported a case in which pathological evidence of trauma to the spinal cord existed coincidentally with the characteristic neuropathology of amyotrophic lateral sclerosis. These changes are manifested by reduction in pyramidal cells of the motor cortex, demyelination of the pyramidal tracts, and loss of the anterior horn cells of the spinal cord.

Clinical description. Atrophy of muscles, fibrillary tremors, spasticity, exaggerated tendon reflexes, and positive Babinski's signs are characteristic neurological findings of amyotrophic lateral sclerosis.

The mental symptoms are those of a chronic brain disorder but are not characteristic of the disease. Memory loss, difficulty in attention and concentration, emotional instability, and unmotivated laughing and crying may occur. There is usually a depressive reaction, associated with an awareness of the progressive nature of the disease. Some authors

consider the mental symptoms to be fortuitous, and others think the mental symptoms are directly related to brain changes.

Prognosis and treatment. The prognosis is inevitably bad, since the disease progresses to a fatal issue in 1 to 3 years after the appearance of the first symptoms. There is no treatment useful in controlling the progress of this disease. Some relief from discomfort may be obtained from the use of tranquilizers, particularly those that tend to have a muscle-relaxant effect, such as Valium and meprobamate.

Cerebral Palsy

The term "cerebral palsy" refers to a variety of conditions in which there is a motor deficit resulting from defect of or injury to the motor centers or pathways in the central nervous system. The term derives its usefulness from the fact that it describes a group of patients who require similar specialized programs of therapy, management, and education. It applies to sequels of brain disease, particularly when the disease is congenital in origin. It is not usually thought of in connection with progressive disorders or the active phase of an acute disease process. Generally, it applies to illnesses that lead to disability during childhood. It covers such disorders as hemiplegia, spastic diplegia or paraplegia, complex diplegia or quadriplegia, choreoathetosis and related dystonic states, and ataxia.

Etiology. The etiology is some kind of intrauterine defect or birth injury resulting in damage to the motor system.

Clinical description. Such patients have weakness or paralysis of involved motor structures with incoordination and dystonic movements often occurring as a prominent feature. Not infrequently there are also choreoathetotic movements on the involved side.

Mental changes do not occur as a consistent manifestation of any of these conditions but occur only in those cases in which the cerebral involvement is of such nature as to produce mental disability. The condition is not commonly complicated by mental symptoms. The most common manifestation is a motor disorder. In some instances it may be associated with a degree of mental retardation.

Prognosis. The condition is not progressive or degenerative. With appropriate training and exercises, considerable improvement is possible.

Treatment. Since the manifestations of this condition are extremely variable, the treatment must be directed at the specific symptomatology the patient presents. In those instances where mental changes occur, curative treatment offers little of value; hyperactivity or disturbing behavior may be controlled by appropriate tranquilizing medication.

Creutzfeldt-Jakob Disease

This is a diffuse degenerative lesion involving both the pyramidal and extrapyramidal systems. The condition usually occurs in the presenile period. There is

some indication that it may be a deficiency disease. The actual cause of it is not known, and it is probably better considered as a degenerative condition.

Clinical description. Warick et al. suggested that a number of similar disorders in which the etiologic factors are unknown should be grouped together. They described three stages of the disease, the first characterized by mental changes of depression, anxiety, loss of interest, memory loss, and episodes of inconsistent behavior. These become associated with some disturbances of gait, loss of sleep, and impairment of speech. The second stage is characterized by overt psychotic and neurological changes, with progressive narrowing of interest, confusion, agitation, apathy, and intellectual deterioration. The third or terminal stage is characterized by extreme dementia, generalized hypertonicity, and profound speech disturbance.

The condition should be considered a progressive degenerative disease with the mental symptoms of a chronic brain syndrome. The usual course is about 1 year, and it usually occurs in the 3rd to the 5th decade. The first manifestations are usually those of irritability, anxiety, and depression, with gradual development of various motor disturbances. There are no characteristic mental changes, but the findings rapidly become those of a severe dementia.

Prognosis and treatment. The prognosis is inevitably bad, and there is no known treatment.

Suggested Cross References

Schilder's disease and cerebral palsy, which are mentioned in this section, are presented in terms of their effects on intellectual functioning in Chapter 22, on mental retardation. Paralysis agitans, subacute combined sclerosis, Friedreich's ataxia, Huntington's chorea, and amyotrophic lateral sclerosis are further discussed from a neurological point of view by Solomon in Chapter 10 on neurology.

Chapter 20

Brain Disorders. III: Associated with Trauma, Poisons, Drugs, Infection, and Neoplasm

20.1 BRAIN SYNDROMES ASSOCIATED WITH TRAUMA

HENRY W. BROSIN, M.D.

Introduction

The need for careful review of the medical status of brain disorders associated with trauma has become increasingly evident. On the one hand, the diagnosis, evaluation, and treatment of head injuries have become more complicated. Concurrently, psychiatric syndromes following injury to the head are of growing medical interest because of their frequency, severity, and medicolegal importance.

Changing medical concepts. Prior to 1940, psychiatrists and neurologists were concerned primarily with the demonstrable organic damage which resulted from head injury, and with the treatment of gross sequelae, such as epileptiform attacks and major deviations in behavior, which were readily apparent. However, over the past 40 years, physicians have gradually come to realize that injury to the head does not necessarily involve injury to the brain. Nor does brain injury inevitably result in demonstrable disabling symptoms or mental disorders.

In brief, current medical concern is no longer restricted to the nature and residual effects of permanent brain damage. It has been extended to apply to all syndromes following head injury, which may, or may not, involve brain damage. And, concomitantly, clinicians have become aware of the innumerable complex and subtle variables which must be considered in connection with such phenomena. These include the patient's pretraumatic personality (including his capacity for object relationships, and the conscious and unconscious factors which governed his relations with other people); his occupational and

domestic history; and, in some cases, the circumstances of the accident itself. Investigation of the patient's post-traumatic behavior is equally crucial, of course. And, in fact, although evaluation of the complex interaction of psychosocial variables is an inherent part of psychiatric practice, perhaps nowhere is a more intricate combination of organic, social, and psychological components encountered than in the stages of adaptation following head injury.

Medicolegal implications. Finally, as mentioned above, current interest in head injuries can be ascribed to their increasing medicolegal importance. According to the National Safety Council, approximately 10,200,000 injuries due to accidents were reported in 1963. It is further estimated that many of these accidents (which occurred at work, were due to motor vehicles, etc.) involved head injury. In recent years, a larger proportion of the victims of such accidents have been insured against personal injury; an increasing number of psychiatrists work for industry; and to ensure the equitable settlement of such legal actions, the court must exert more compelling pressures on plaintiff and defendant alike. The presence of brain damage is rarely disputed, although the precipitating events may be the subject of endless legal debate. However, many attorneys, claims adjusters, and medical examiners fail to recognize that head injuries which do not involve brain damage may be equally debilitating, although such after-effects may be transient. Nor are the subtle symptoms which may accompany such traumata fully understood.

In summary, it has become increasingly apparent that the accurate legal assessment of syndromes following head injury and the efficacy of treatment in such cases (regardless of the presence or absence of brain damage) depend on further understanding of the neurological, biosocial, and psychological factors involved.

Overview

Nosology. The classification of brain disorders associated with trauma delineated in *The Standard Nomenclature of Diseases and Operations* issued by the American Medical Association, has been adapted by the American Psychiatric Association (A.P.A.) for inclusion in its *Diagnostic and Statistical Manual, Mental Disorders* (and is almost identical with other national and international nomenclatures). This classification is used here as well, as the most comprehensive—yet the simplest—nosology available.

Nomenclature. According to the official nosology, the application of the word “trauma” in this context is restricted to designation of *physical injury* to the head, unless otherwise indicated. Thus, this limited use of the term is distinguished from the broader concept employed by many psychiatrists, who, following Freud’s theoretical formulations, have extended it to include various social or psychological events and experiences, internal or external, which precipitate feelings of sudden danger, fright, and helplessness, and which, in turn, trigger regressive defenses, giving rise to symptom formation.

The classification of brain disorders caused by or associated with trauma, within this frame of reference, is listed below.

- Acute brain disorders
 - Disorders due to, or associated with trauma
 - Acute brain syndrome associated with trauma
- Chronic brain disorders
 - Disorders associated with trauma
 - Chronic brain syndrome associated with birth trauma
 - Chronic brain syndrome associated with brain trauma
 - Chronic brain syndrome, brain trauma, gross force
 - Chronic brain syndrome following brain operation
 - Chronic brain syndrome following electrical brain trauma
 - Chronic brain syndrome following irradiational brain trauma

Diagnosis. Recent methodological advances in the study of brain function, made possible by new instruments, including computers, would seem to proclaim concomitant improvements in methods for the clinical diagnosis, evaluation, and recording of the changes in the brain, and in the behavioral patterns of the brain-damaged patient. Yet, despite these advances, essentially, the clinician is as dependent on clinical observation of patients (the natural history method) today as he was in 1787, when Benjamin Bell wrote his outstanding description of concussion.

Assessment of behavioral defects. The behavioral defects associated with acute head injury may be relatively simple or highly complex. In addition to the routine physical and laboratory examination for anatomic and physiological dysfunction, the testing of a comatose or unresponsive patient involves the neurological examination of his sensory, motor, and reflex functioning. Immediately after the patient has regained consciousness, behavioral defects can be detected by careful examination of his mental status.

The battery of tests devised by Henry Head for aphasia in 1920 has proved most useful for this purpose: (1) recognition and identification of objects; (2) recognition and identification of colors; (3) the man, cat, and dog tests; (4) the clock tests; (5) the coin-bowl tests; (6) the hand, eye, and ear tests; and (7) reading, writing, and drawing puzzles.

These simple tests do not require complex psychological testing equipment. Nevertheless, they represent effective methods for evaluating the patient’s mental functioning, in terms of such standard parameters as orientation to person, place, and time; memory for recent and remote events; vocabulary; serial subtraction and simple arithmetic; and capacity for abstract thinking, as demonstrated by interpretations of proverbs, similarities and contrasts, and stories. During the anamnesis and testing, the nature and quality of the patient’s mental functioning, the relevance and coherence of his thoughts, and his general intellectual ability are noted. The patient’s mood and affective state, his relation to other people, and his attitude toward various topics are also considered. His insight into and reaction to his current injury are particularly significant. Occasionally, the nature of the accident itself produces reactions of overpowering fright, panic, helplessness, or confusion which are reminiscent of the reactions of soldiers who have experienced acute stress in battle. These reactions may “trigger” psychiatric symptoms which, in fact, are not related to the brain injury. In any event, after some weeks or months, more elaborate tests may be administered to establish the precise nature and severity of the deficit.

Finally, there is ample evidence that many patients whose persistent complaints are not justified by the severity of their head injuries had difficulties in their interpersonal relations prior to their accident. For example, Ruesch, Harris, and Bowman studied 125 patients with chronic post-traumatic syndromes and 140 control patients, 70 of whom had suffered acute head injuries. Not surprisingly, those patients in the control group with acute injury and obvious organic damage had more complaints than those whose head injuries did not involve brain damage. On the other hand, those patients who had suffered minimal injury were apt to have more complaints than patients with gross brain damage and chronic brain disorders. Moreover, their complaints tended to increase and become more diffuse with time.

Treatment. In the past 2 decades, with greater understanding of the sequelae of head injuries, the views of most workers in this field with regard to the treatment of patients who have suffered such traumata have been altered considerably.

The establishment in general hospitals of special trauma centers, which are specially equipped for the diagnosis and emergency neurological and physiological treatment to such patients, is a universal recommendation. Many investigators believe that a psy-

chiatric evaluation should be a routine part of this diagnostic work-up. And, in fact, the clinical evidence has demonstrated that this procedure, when combined with subsequent formal psychiatric interviews, where indicated, facilitates the patient's recovery.

Apart from such emergency measures, the crucial importance of supportive medical and psychological care by physicians, nurses, and hospital staff in the early phases of the patient's illness cannot be overemphasized. The fact that such procedures can eliminate (or, at least, diminish) the undesirable sequelae of head injuries is generally recognized. Certainly, this is borne out by the proven effectiveness of multidisciplinary teams (such as the one developed by Howard A. Rusk at New York University's Institute of Physical Medicine and Rehabilitation) in reestablishing functional competence in patients with anatomic impairment or disability.

An equally crucial determinant of clinical progress is the attitude of the patient's family and friends toward his injury. Sir William Osler stated that "tuberculosis is a social problem with medical aspects." A similar statement can certainly be made about head injuries. Careful attention to the total patient in his environment as well as the clinical setting is absolutely essential for his optimal recovery. To elaborate on this very briefly, Paul Schilder pointed out that in our society even a minor injury to the head is usually the source of greater anxiety and emotional conflict than is a serious injury to an arm or leg. In susceptible patients, the daily impact of the minor pain or transient disability produced by head injuries may lead to anxiety, discomfort, and fatigue, which in time may be organized into patterns of neurosis and invalidism. The sequelae of head injuries may also produce primary and secondary gains similar to those associated with neuroses and character disorders. In fact, in a study he conducted in 1942, Sir Aubrey Lewis found that in many instances no essential distinction could be drawn between the behavior of patients with conventional neuroses and those who suffered from the chronic effects of head injury. These findings were subsequently confirmed in 1945 in a similar investigation by Ruesch, Harris, and Bowman.

Acute Brain Disorders Due to or Associated with Trauma

Definition. This category is described as follows in the A.P.A. *Diagnostic and Statistical Manual*:

Here are to be classified those cases of acute brain syndrome developing immediately after head injury produced by external trauma of a gross physical nature, including surgery. Mental disturbances following injuries to other parts of the body are not to be classified here. Brain syndromes in which head trauma acts as a contributing or precipitating cause should be diagnosed under the proper etiological heading and not included in this group. This category does not include the chronic organic results of head injury.

Accordingly, concussion, traumatic coma, traumatic delirium, and Korsakoff's (amnesiac-confabulatory) syndrome are usually subsumed under this heading, although they are not specifically classified as such in the *Standard Nomenclature*.

Psychological reactions to acute brain disorders. The psychological reactions to organic cerebral deficit, as described by psychiatrists and neurologists, may take various forms: The patient may be consciously or unconsciously aware of his defects, to varying degrees, and he may try on a conscious or unconscious level to overcome and, in general, to avoid awareness of these defects in many ways. The defense mechanism of denial (of defects) is typical in such cases. Confabulation, that is, the attempt to replace memory loss by fantasy or reality which, however, is inappropriate to the occasion, is equally common among this patient population. Irritability often represents an expression of the patient's anger at his inability to perform; it is also a way of reducing the tension inherent in those situations which threaten the patient's uneasy equilibrium. Even those patients who seem placid, or even euphoric, can often be easily upset by searching questions and may employ crude and inappropriate humor in an effort to ward off threatening persons and experiences.

Prognosis. The prognosis for such disorders will depend on the nature of the lesion, the patient's pretraumatic personality, the efficacy of treatment, and environmental factors. Under optimal circumstances, final evaluation of the residual loss of function can be made from 12 to 18 months after the injury. The central nervous system has excellent recuperative powers, so that this final assessment should reveal that for the most part, if not entirely, the patient's mental functioning has been restored to normal, as demonstrated by psychological test findings, psychiatric examinations, and observations of the patient's behavior by his family, friends, and employer.

Concussion

Clinical description. Concussion is caused by a head injury, resulting in an interruption of brain function which is accompanied by a loss of consciousness. Usually, the loss of consciousness is of brief duration and is followed by spontaneous and complete recovery, although there may be brief (post-traumatic) amnesia for the events which occurred a few moments prior to the injury. In other cases, where the loss of consciousness is more prolonged, there may be a sudden awakening without psychiatric sequelae; or, on the other hand, the patient, despite his apparent consciousness, may manifest post-traumatic amnesia, confusion, and disorientation. For example, boxers have been known to continue to box or to perform some routine activity following a concussion for many hours before they become fully oriented once again.

The clinical significance of the duration of loss of consciousness, or, more specifically, the possible correlation between the duration of loss of consciousness and the extent of the injury to the brain (as measured by the severity of psychiatric sequelae) has been the subject of considerable controversy. It is generally agreed that no such positive correlation can be established in instances where the period of unconsciousness is relatively brief. The symptoms in such cases, which typically include headache, apathy, dizziness, dullness, inability to concentrate, defective memory, irritability, fatigue, insomnia, and decreased tolerance for noise, light, heat, and alcohol, usually subside within 6 weeks after the injury, without evidence of permanent damage. If these symptoms persist, however, or if other symptoms denoting impairment of brain function appear after restoration of consciousness, the patient should be reexamined carefully for new evidence of brain damage, and intensive treatment should be initiated. Most authors believe that when there is no evidence of brain damage, but the patient has a delayed reaction to the injury, in all probability those symptoms which appear or become more severe a few days or weeks after the injury are psychoneurotic in origin.

From the neuropathological point of view, concussion is usually attributed to numerous minute, but definite, contusions, lacerations, and hemorrhages in the brain. A few authors postulate neuronal disturbances at the submicroscopic level. These disturbances may produce changes in the surrounding fluids and altered electrical discharge, which may render the patient unconscious.

Perhaps there are delayed changes in the nerve cells themselves which are vital to the development of the chronic brain syndrome following head injury. Interestingly, after brain trauma, there is usually little change in spontaneous electrical activity at various levels of the central nervous system, although occasional flattening and slow wave activity are seen.

Recent experimental work on monkeys at the National Institute of Neurological Diseases and Blindness has shown that similar organic damage (contusions, swelling, and hemorrhage) may accompany a whiplash injury. This type of injury results when the head is suddenly jerked forward and then backward (when one's car is hit in the rear, for example). While often there is no external evidence of injury immediately, symptoms typical of head injury may develop subsequently. Air studies, arteriograms, and echoencephalography may be used to establish the presence of organic injury in such cases.

Finally, in a series of over 1,000 head injuries studied by Sumner, the frequency of post-traumatic anosmia was 7.5 per cent. Primary and secondary cerebrospinal fluid rhinorrhea have also been seen occasionally. In closed head injuries, pneumoencephalographic findings are a valuable diagnostic aid. Diffuse and more or less symmetrical enlarge-

ment of the ventricles, with dilation of the third ventricle, has been reported in post-traumatic psychosis.

Treatment. The treatment of concussion will, of course, vary with diagnosis of the extent of the injury to the brain and the rest of the body. However, in general, both the physical and the psychological sequelae of concussion require attention. During the state of unconsciousness, the tongue falls back, blood and vomitus accumulate, and the patient's breathing may be obstructed. Thus, the physician requires some knowledge of tracheal intubation and bronchoscopy if he is to maintain an open airway; in addition, blood loss must be estimated accurately, and shock must be treated promptly.

In most patients suffering from mild concussion with closed head injury, the early stage of neurogenic shock passes quickly; if it persists, every effort should be made to determine the cause. Such phenomena may be due to bleeding inside the head or in the body, metabolic disturbances, renal dysfunction, or damage to vital central nervous system centers. Subdural hematoma must be kept in mind, as well. (Carotid angiography is considered an extremely useful procedure for diagnosis of this lesion.)

With respect to medication, most physicians avoid the use of narcotics and stimulants in the treatment of concussion. If sedatives are required to facilitate bed rest, paraldehyde is usually considered the drug of choice because it does not disturb pupillary signs, is relatively nontoxic, and is easily eliminated. Minimal use of mechanical restraints and headboards is recommended. The patient should be kept reasonably warm, but every precaution should be taken against burns from hot water bottles, heating pads, etc. While x-rays of the skull are desirable to detect fractures and their possible sequelae, the physician may be justifiably reluctant to request such procedures if the patient is restless or shows signs of cerebral compression or shock. If the patient becomes unconscious after an interval of consciousness, a neurosurgeon should be called in for consultation without delay, for the patient may be suffering from extradural, subdural, or intracerebral hemorrhage, cerebral edema, or meningitis. Finally, after all medical and surgical procedures have been completed, continued bed rest and observation of the patient, with special attention to vital signs and indications of delayed bleeding, are essential.

Psychological factors must be considered from the outset. From the time the patient is first seen, the physician in charge should take steps which will enhance his recovery and minimize those factors which may contribute to the formation of neurosis. Admittedly, psychiatrists are rarely consulted as a matter of routine at an early stage in the treatment of such patients. However, physicians who are aware of the value of a comprehensive treatment program should include psychiatric care where there is unusual anxiety, depression, and preoccupation with

morbid concerns. Apart from the benefits derived from these formal treatment procedures, patients have attached great significance to the attitudes and behavior of physicians, nurses, and other hospital personnel immediately after they regained consciousness and in the early post-traumatic phase of their recovery. Similarly, friends and relatives may engender—or alleviate—the patient's anxiety, fear, or guilt by their attitudes and what they say.

Traumatic coma

Clinical description. Traumatic coma is characterized by a profound loss of consciousness, similar to that suffered in concussion, together with the absence of voluntary motor activity and failure to respond to stimuli. Coma is usually regarded as severe and prolonged if it persists for more than 2 hours; even a semicomatose state, in fact, which lasts for 24 to 36 hours without improvement may indicate brain tissue contusion and should arouse concern for the welfare of the patient. Changing neurological signs, blood in the cerebrospinal fluid, increased intracranial pressure, or electroencephalographic and x-ray evidence of fracture should alert the physician to rising intracranial pressure (as, for example, in subdural hematoma) and the possible need for surgical intervention.

Treatment. If such intervention is necessary, psychiatric care should be considered after surgery to minimize symptom formation and invalidism and to prepare the patient for whatever rehabilitative procedures may be required. Traumatic coma may be followed by stupor, traumatic delirium, Korsakoff's syndrome, or a clearing of consciousness.

Traumatic delirium

Clinical description. Delirium is a disordered state of consciousness which may occur in many toxic, disturbed metabolic, or febrile states, as well as in cases of head injury. Furthermore, since a similar state of personality disorganization may be precipitated by emotional factors, it is not always easy to estimate the role of organic factors. Delirium is characterized by partial disorientation for time, place, and person; confusion; disordered sensorium; and restlessness. It is often accompanied by anxiety and irritability. These variables usually fluctuate in character and depth. However, several specific behavioral patterns have been observed, and this syndrome is easily identified. Some patients behave as though they cannot understand what has happened to them, belligerently demand to be released from the hospital, or demand that they be detained just as belligerently, for their own self-protection. Other patients wander about in a daze and require constant supervision to prevent accidental injury.

Treatment. Delusional patients, particularly paranoids, require special nursing care to prevent them from attacking personnel, who are misidentified as

enemies; from inadvertently hurting themselves while escaping from imagined enemies; and from committing suicide. Apart from such specific considerations, delirium, which lasts for longer than a week, usually indicates the presence of serious brain damage. However, the final assessment of brain damage should not be made for a year, for mental and focal defects frequently clear up spontaneously.

Korsakoff's syndrome (amnesiac-confabulatory)

Clinical description. Korsakoff's syndrome is a psychiatric disorder which may follow an acute delirium, twilight state, or stupor. In its classical sense, Korsakoff's syndrome is associated with chronic alcoholism, polyneuritis due to thiamine (vitamin B₁) deficiency, and, occasionally, pellagra-like skin lesions. Obviously, however, in those cases which are caused by head injury, there is no evidence of neuritis or dermatitis unless there is a coincidental severe thiamine deficiency.

Frequently, but not always, such patients evidence conspicuous memory loss. Concurrently, the mechanism of confabulation, described above, is often employed to compensate for this deficit. It has been hypothesized that this memory failure is not due to the defective storage of information. Rather, it is due to a lack of access to the information in storage and to the lack of new input. In addition to possible memory loss, confusion, severe disorientation, and amnesia for recent events are present, but the principal defect is the patient's inability to form new associations. The questions asked in the routine mental status examination to test the accuracy of the patient's perception, memory, attention span, capacity for abstract thinking, etc., will usually reveal marked defects. In contrast, this may or may not be true of patients with acute brain disorders due to surgery (e.g., brain tumor or lobotomy) or immediately following electric convulsive treatment.

Chronic Brain Disorders Associated with Trauma

Definition. In the American Psychiatric Association's *Diagnostic and Statistical Manual*, Chronic Brain Disorders associated with brain trauma are defined as follows:

Here will be classified the post-traumatic chronic brain disorders, which produce impairment of mental function. Permanent brain damage which produces only neurologic changes because of its focal nature, without significant changes in the areas of sensorium and affect, will not be classified here. Generally, trauma producing a chronic brain syndrome would have to be diffuse and would have to leave permanent brain damage. Post-traumatic personality disorder associated with chronic brain syndrome will be placed in this group with the appropriate qualifying phrase.

If the brain injury occurs in early life, it may manifest itself primarily in a developmental defect of intelligence. . . .

A head injury may usher in, or expedite the course of, a chronic brain disease, especially cerebral arteriosclerosis. The differential diagnosis in such cases may be extremely difficult. If the case history shows symptoms of circulatory disturbance,

particularly arteriosclerosis, before the injury, and the physical examination confirms the presence of arteriosclerosis, the case will be classified under Chronic Brain Syndrome associated with cerebral arteriosclerosis.

To elaborate on this concept very briefly, as mentioned earlier, it is difficult to evaluate the nature of the post-traumatic process in an individual patient because there are no valid methods available for the quantitative measurement of anatomic damage or alterations in physiological, biochemical, electrical, or psychological function. Only rarely do symptoms which exert a manifest effect on behavior persist for more than a year; most patients do not demonstrate marked residual changes after 2 years have elapsed. Consequently, if a patient shows an obvious change in personality or has specific and severe complaints 2 years after a head injury, he will fall into one of the chronic groupings. Nevertheless, the clinician is urged to make a primary diagnosis (e.g., of arteriosclerosis, psychoneurosis, or outright malingering), whenever appropriate.

Nomenclature. There is no uniform nomenclature for the clinical entities subsumed under this major heading. Most authors follow the classifications indicated below, more or less, because of their clinical and medicolegal value: (1) post-traumatic personality disorders; (2) traumatic constitution (Meyer); (3) post-traumatic general cerebral syndrome (Foerster); (4) minor contusion syndrome (Symonds);

(5) encephalosis (Ritter); (6) traumatic encephalopathy; (7) traumatic psychopathic constitution (Ziehen); and (8) postconcussion syndrome.

The assumption underlying each of these conditions is that organic brain damage—not neurosis—causes a chronic impairment of brain function, which results in altered behavior, usually accompanied by symptoms which can be identified as *directly* related to this organic damage, whether anatomic, biochemical, or electronic. The major problem posed by this assumption of significant organic damage, although it may appear to be justified by inference, experience, and autopsy studies, is that it cannot be demonstrated, nor can it be disproved, by physical examination: gross neurological signs of a disordered nervous system are encountered only rarely. On the other hand, evidence of changes in deep or superficial reflexes, vasomotor functions, motor skills, coordination, or sensory organization are usually not impressive enough to be convincing. A second underlying assumption is that either true psychoneurotic processes or conscious malingering, or both, may be associated with the organic damage.

Pathology. Organic sequelae to brain injury are usually thought to be due to the direct effect of the trauma on the brain or surrounding tissue; this effect, in turn, is due to changes in circulation and hemorrhages (as demonstrated in Figure 1). Changes are seen in the ganglion and glia cells, blood vessels,

FIGURE 1. Recent contusion, orbitofrontal cortex. There are pallor, swelling, early fragmentation of parenchyma, patchy nerve cell loss with remaining neurons showing acute changes, numerous petechial hemorrhages. Hematoxylin and eosin. 200 \times . (Courtesy of Dr. John Moosey, University of Pittsburgh.)

FIGURE 3. Old contusion foci, orbitofrontal and temporal. (Courtesy of Dr. John Moosey, University of Pittsburgh.)

choroid plexus, the meninges, and the subarachnoid and subdural spaces they enclose. These changes vary with the nature, location, severity, extent, and duration of the injury. Figure 2 shows the gross appearance of bloody discoloration, contusions, and lacerations of the brain. The atrophy, scarring, and trau-

matic destruction of the brain may be seen in Figure 3. Subdural hematoma with encapsulating membranes is shown in Figure 4.

Around the area of injury there may be anemia, numerous minute hemorrhages, and foci of softening or scars. The normal arrangement of the cellular layers may be altered, with the usual evidence of injury and attempts at repair (see Figure 5). Atrophy is commonly found at autopsy. Ventricular distortion and meningoencephalitic adhesions are sometimes demonstrated in encephalograms and ventriculograms. However, most authors warn against trying to diagnose the nature of head injuries from electroencephalographic findings. There may be a fracture of the inner table of the skull, even though the external table remains intact.

Diagnosis. Although generalizations are not useful because of individual variations, a careful check of the criteria listed below will help the physician to distinguish between symptoms due to organic factors, as opposed to those which are due to pretraumatic personality disorders: (1) roentgen evidence of skull fracture; (2) bloody spinal fluid; (3) bleeding from skull orifices (especially from the ears); (4) focal neurological signs; (5) convulsive states proved to be post-traumatic; (6) ventricular distortion proved to be post-traumatic; (7) history of prolonged loss of consciousness; (8) headache which occurs periodically, is throbbing, and may be altered by postural change (stooping) or physical exertion; (9) sluggish mental functions, in a sanguine patient; (10) continuous symptoms which cannot be modified by suggestion; (11) the patient's interest in rehabilitation, rather than compensation; (12) a continuity and consistency in the development of symptoms after the injury; and (13) results of psychological testing (by the procedures described earlier).

Often, a definite diagnosis cannot be made in dif-

FIGURE 4. Subdural hematoma with encapsulating membranes. (Courtesy of Dr. John Moosey, University of Pittsburgh.)

FIGURE 5. Old contusion, orbitofrontal cortex. There are derangement of architecture, loss of nerve cells, diffuse astrocytosis with microcystic change, and pigment-laden phagocytes. Hematoxylin and eosin. 200 \times . (Courtesy of Dr. John Moosey, University of Pittsburgh.)

ficult cases until the patient has been carefully re-examined at regular intervals over a prolonged period. Apparently, some patients who have suffered severe injuries and prolonged loss of consciousness may recover without detectable organic or psychological deficit. In contrast, patients with apparently minor injury to the head may prove to have suffered significant brain damage.

Psychiatrists have a valuable contribution to make to both diagnosis and therapy in these cases. Repeated careful examination of the patient's mental status will often reveal hitherto unsuspected disabilities in the perceptual, cognitive, affective, and executive spheres. Evidence of changes in abilities, moods, and personality patterns which have their onset at the time of the trauma are suggestive of organic damage, particularly if the patient has functioned well previously.

Psychological reactions to chronic brain disorders associated with trauma

General theoretical formulations. Disturbed ego functioning following trauma, used in a broader sense to refer to massive or life-threatening stress, has been discussed by Freud, Hollós and Ferenczi, Goldstein, Schilder, and Kardiner.

A traumatic experience triggers a neurotic reaction in which the event is interpreted, because of guilt feelings, as a punishment by parental figures or an

impersonal fate, as a threat of loss of parental love and protection, or even as a direct attack, which is the equivalent of earlier fantasies of castration. The ego regression engendered by the feelings of helplessness, hopelessness, and fear which this interpretation gives rise to results in the restriction of ego functions. Since the adult finds such restriction intolerable, he engages in persistent attempts at experimental mastery. If these fail, his anxiety increases with concomitant loss of confidence and fear of anticipated dangers. The sleep disturbances which are so common in these cases (and in the war neuroses, as well) have been interpreted as repetitive attempts to master the noxious emotions associated with the traumatic event.

If a patient who has a strong need to feel superior to his environment suffers a humiliating failure or accident, his internal controls (superego) or external controls may not be strong enough to keep him from using unconscious neurotic defenses (hysterical amnesia and paralyzes, obsessional, paranoid, or hypochondriacal preoccupations) or from seeking secondary gains through fiscal compensation or sympathy from his family and colleagues. Because these potential secondary gains may seem attractive and are achieved at a seemingly low psychic cost, some patients will be tempted to take advantage of the situation if they are not helped to see that invalidism is ultimately self-defeating.

In fact, however, it is the experience of physicians working in this field that conscious malingering is rare and can be detected relatively easily. There may be some exaggeration of neurotic complaints, but neuroses are genuine clinical conditions which are beyond the conscious control of the patient. The defensive behavior patterns seen in other patients with organic brain disorders or systemic diseases are seen in this patient category as well. These include irritability, as a sign of general dissatisfaction or fear of a potentially threatening situation; impaired memory; restricted interests; apathy, which represents defensive withdrawal from external threats; and increased preoccupation with self. The last of these patterns is precipitated by the patient's realization, on both a conscious and unconscious level, that his capacities for thought and action have been seriously impaired.

Patients in this category may also be burdened with the knowledge that they are vulnerable to injury and death, which disturbs earlier images of omnipotence. Depressive moods are common, and compensatory periods of euphoria are rare. Defense mechanisms, such as projection, displacement, and rationalization, appear with alterations in the crucial ego functions of integration, sensory perception, and motor and executive control. At the same time, the ego is less able to control discharge of id impulses, and there is a deterioration in the patient's functioning in the external world, in the domestic, occupational, or socioeconomic spheres. However, one factor is of crucial importance in determining the severity of these symptoms: as mentioned earlier in this section, for many sensitive people, injury to the head has special emotional significance. Those patients who do not overevaluate the head may not have the same intense concern about such injuries. Nor will their symptoms be as severe.

Concomitantly, several investigators have expressed some doubt as to whether the progressive deterioration of the patient's behavior which is so common in cases of chronic brain disorder can, in fact, be attributed to head injury alone, in the absence of other organic or psychosocial factors. The finding, cited earlier, that most patients with poor adaptation following a head injury had a prior history of poor adaptation would seem to lend support to this speculation.

For example, Schaller found that headache occurred frequently in only 23 per cent of the postcontusional cases he studied, although 97 per cent of the neurotic patients investigated complained of headache frequently.

In Anderson's series all patients who did *not* complain of headaches showed neurological signs of brain injury. The comments cited earlier by Sir Aubrey Lewis merit repetition in this connection. In brief, on the basis of detailed studies of these patient groups, Sir Aubrey Lewis concluded that, in

many instances, there was no essential difference in the behavior patterns of postcontusional patients and those with a common neurosis. Ruesch, Harris, and Bowman also found that, in a large proportion of their patients, brain damage itself was of secondary importance; the pretraumatic personality was of primary importance in determining the nature of the post-traumatic clinical state. The contention that injury to brain tissue, in itself, cannot adequately explain mental deficit has been further borne out by clinical investigations similar to that conducted by Bruell and Albee, who reported on a patient who showed no behavior defects following hemispherectomy for a brain tumor.

In short, in cases of deterioration due to aphasia, epileptiform seizures, deafness, motor weakness, or paralysis, which ostensibly resulted from brain injury, two possibilities must be carefully investigated: the presence of a preexisting idiopathic convulsive state, cerebral vascular attack, or arteriosclerotic confusion; and, secondly, the patient's pretraumatic personality.

Psychiatric treatment. The treatment programs should emphasize support by the medical team, the family, the rehabilitation team, and other significant figures, where indicated. Brain-injured patients may seek quiet and rest initially, in order to collect their energies, allow the disturbed ego functions to heal, and gradually regain ego mastery. They may also try to regain mastery by active attempts to deal with repetitive belated discharges, such as nightmares, motor discharges, and other emotional activity. The psychiatrist can facilitate rest by reassurance and by satisfying the patient's passive-dependent wishes, or he may facilitate the patient's efforts at active mastery by utilizing such methods as active catharsis, which encourage the patient to relive the traumatic experience, and conscious analysis and clarification of the disturbing conflicts. Skill and experience are required to use both methods to advantage. Grinker and Weinberg recommended narcotherapy or hypnosis for severe anxiety or regressive states associated with such disorders.

Finally, it is the general consensus that financial compensation over a long period of time may be a deterrent to therapeutic progress. Therefore, most authorities favor lump sum settlements where justified.

Chronic brain disorder: Simple type. This diagnosis is made when the patient complains of headaches, dizziness, irritability, fatigue, insomnia, and poor tolerance for excitement, alcohol, sunlight, and exertion. Anxiety is usually a prominent symptom and may be interpreted as a signal system to help the patient ward off noxious psychological stimuli.

Traumatic encephalopathy with deterioration. This diagnostic category differs from other forms of organic brain disorders in degree, but not in kind. If

it can be shown that there is a definite loss of skills not due to any other causes, then presumably this loss is a result of the head injury. In this disorder, the symptoms and signs described earlier appear in more severe form. And, in addition, the patient may demonstrate a loss of initiative and sense of responsibility, an inability to plan for the future, and a lack of concern about factors which are not of immediate concern. Ego controls, especially the repression of unconscious impulses, continue to fail, and as ego defenses become less effective, impulses are discharged in cruder form.

A diagnosis of traumatic encephalopathy with deterioration requires definite evidence of the loss of specific skills. The physician must then eliminate any other factors which might account for this impairment in brain functioning, before it can be finally attributed to head injury.

Chronic brain disorders with convulsive states (traumatic epilepsy). A lack of knowledge with regard to the pathophysiology of convulsive states precludes clear differentiation of the post-traumatic cases (where the epilepsy is a sequelae of brain injury) from those which derive from preexisting conditions. The work of Penfield and Jasper and others on the surgical removal of focal lesions was a major advance in demonstrating that post-traumatic cerebral lesions can cause convulsions. Another advance was the postulate that idiopathic epilepsy was not predominantly hereditary but was often the result of traumatic, toxic, and infectious diseases in infancy. This hypothesis is currently receiving strong support from many quarters, including those workers who are engaged in studies of the battered child syndrome.

Treatment. Drugs play an important part in the treatment of traumatic epilepsy. However, their use for sedation or stimulation has not been clearly defined, primarily because of the paradoxical reactions in brain-damaged children.

Traumatic encephalopathy due primarily to head trauma with secondary psychogenic symptoms. Compensation cases, which require a greater precision in demonstrating both the organic and the psychological components of a post-traumatic state, are often classified under this heading. More specifically, it is essential in such cases to relate all objective signs of brain injury to the subjective complaints and altered behavior of the patient, for there is ample documentation that the latter, in particular, may occur in the absence of injury to either the brain or the body. Apart from such considerations, the patient's pretraumatic personality, the psychological and socioeconomic circumstances under which the injury occurred, and the post-traumatic personality reorganization are often crucial determinants of the course of convalescence.

Post-traumatic functional disorders due secondarily to head injury

Post-traumatic hysteria. Frequently, patients seen in the emergency room of the general hospital following head trauma do not manifest organic injury (according to the criteria listed above). Rather, their post-traumatic disorders are hysterical in origin. In fact, almost any form of neurotic reaction may be precipitated by head injury. However, hysterical phenomena occur most frequently. At the same time, it should be pointed out that admixtures of neurotic trends exist in almost all people, and any one of these may be activated in the individual who is so predisposed.

The increased suggestibility of hysterical patients may also lead them to exaggerate the intensity of their injury and to accept eagerly the status which accompanies disability or to demand compensation when such action is suggested by physicians, lawyers, relatives, or friends.

Compensation neurosis. Although this category is listed as a separate entity, psychiatrically it is considered an hysterical process because the unconscious wish for compensation is a powerful factor in symptom formation. Consequently, it has significant medicolegal implications.

On the other hand, even where there is no possibility or question of compensation, hysterical symptoms may occur in many cases of head injury, demonstrating that the compensation motive is not always essential. Another group of patients who consciously express a wish for compensation improve with therapy whether or not such compensation is forthcoming. And still a third group are inaccessible to therapy but recover once they have received lump sum settlements. Apparently, this third group does not represent a large proportion of the post-traumatic population, although the number of such patients may increase once current legislation has made compensation more easily available.

Traumatic neurosis. This term, which is rarely used today, was introduced by Horn in 1916 and subsequently adopted by Wechsler, Strauss, and Savitsky ("terror neurosis"), Ebaugh and Benjamin, and others to designate a relatively specific (but infrequent) panic state in which anxiety and hysteria are prominent. This extreme reaction is typically precipitated by a significant threat to survival, e.g., major disasters involving fire, explosions, and earthquakes. However, it is rarely observed in ordinary industrial or automobile accidents. In this context, trauma refers to both physical injury and noxious psychological factors causing personality disorganization. Theoretically, the psychodynamics of traumatic neurosis differ from those evident in hysteria in that the premorbid personality is free from neurotic predisposition.

Choice of symptoms. As mentioned above, hysterical processes are the most frequent neurotic sequelae to head injury, but other syndromes may be seen as well. The pretraumatic personality probably plays a major role in the choice of symptoms. The familiar obsessional defenses (with or without such paranoid trends as internalization of anxiety with preoccupations, counterphobic attitudes, avoidance of initiative, aggressive attempts at restitution, ritualistic protective devices) or more complete regressive patterns may occur.

Malingering. Most psychiatrists agree that genuine, conscious simulation of symptoms is uncommon. Such actions are difficult to plan and even more difficult to maintain consistently, and the exaggerations of subjective symptoms and overt behavior are usually apparent to the trained observer. Therefore, they are easy to detect during repeated neurological and psychiatric examinations. However, Keschner has described in detail a variety of simulations, involving disturbances of motor power; paroxysmal attacks; and abnormality of movement, sensation, coordination, speech, and the senses, particularly vision and hearing.

Diagnosis becomes more difficult when purposeful simulation is motivated by a genuine neurotic process with hope of secondary gain. Until more physicians and lawyers recognize that neurotic processes are beyond the conscious control of the patient and that these processes are often amenable to psychiatric treatment, the disposition of such cases will continue to involve endless debate.

Acute and Chronic Brain Diseases Associated with Other Syndromes

The relationship between brain injury and psychosis is complex and controversial. The following possibilities must be considered in connection with the claim that a psychosis was precipitated by a brain injury.

1. *The relationship exists as claimed.* As a rule, there is no evidence that brain injury, as such, can precipitate a major psychosis, such as schizophrenia or manic-depressive psychosis in a previously healthy person, but in rare cases, complex phenomena may occur. Such cases have been described by Lewis and by Feuchtwanger and Mayer-Gross.

2. *The patient had a major physical or mental disorder prior to the accident.* Post-traumatic dementia may occur in patients suffering from cerebral arteriosclerosis, chronic alcoholism, or similar diseases. In such cases, it is necessary to investigate the possibility that the accident itself was due to an arteriosclerotic seizure or dizziness. Even in a sick or aging patient, however, the possibility exists that the patient will defend himself against threats to his ego integrity which are typical sequelae to head injury, by the usual psychological defenses.

3. *The patient had a latent physical or mental disorder which was aggravated by the brain injury or its psychological sequelae.* General paresis or psychosis due to syphilis of the meningoencephalitic type is generally considered to represent an organic cerebral disorder which can be activated by an injury, although the claim has also been made for other diseases. In such cases, it is necessary to establish that the accident was not caused by a fall or convulsion resulting from the basic parietic disease.

Recent studies, following Hollós and Ferenczi's investigations in 1925, stress the importance of pretraumatic personality factors in such disorders. But these recent studies have offered convincing evidence in support of the hypothesis that some of the symptoms of paretics are due to organic deficit and related compensatory behavior by demonstrating that some functions of personality deterioration and dementia, e.g., memory loss, grandiosity, euphoria, or depression, are not merely arbitrary or adventitious failures. Rather, they believe that these malfunctions are the result of emotional (motivational) conflicts that can be recognized as meaningful. The most common mechanisms employed in such conflicts are denial, regression, and isolation, but other defense mechanisms can be observed as well. The phenomenon of "flight into health" following recovery from a serious organic disease, such as pneumonia, or a blow on the head, can be better understood in the light of this hypothesis. Finally, although there is no convincing experimental evidence that a head injury can activate general paresis, there is some statistical evidence for this hypothesis.

Chronic brain syndrome following electrical brain trauma. This category is concerned with massive assaults on the brain due to accidental exposure to electricity. There is a 17 per cent mortality among patients in this group. Further, it has been reported that permanent disability was almost always the result of burns, without any psychogenic or other organic complications.

Therapeutic electroconvulsive therapy usually causes some mild impairment of memory of variable duration, but there is no evidence that there is permanent impairment of memory or intellectual deterioration, even when the patient manifests severe disorientation as seen in Korsakoff's syndrome.

Chronic brain syndrome following irradiational brain trauma. Due to an increasing number of reports that small amounts of ionizing radiation had produced behavioral and electrophysiological changes in mammals, the International Atomic Energy Agency sponsored symposia on the effects of ionizing radiation on the nervous system, which were published in 1962 and 1964. Studies of humans have also been described in various U. S. Atomic Energy Commission reports.

There is relatively little published work on the be-

havioral changes in radiated human subjects. Those physicians who have had some acquaintance with patients who are under severe stress due to exposure to radiation report that these patients acted like other patients under comparable conditions. Following the incident, there is, at first a tendency by both the patient and the health physicist to underestimate the dosage considerably. Later, if there are adverse biological responses, there is a tendency to overestimate the dosage.

Conclusions

In summary, much work has been done in recent decades to improve the usefulness of psychological testing in evaluating organic brain injuries. However, although many methods have been developed and the skills of clinical psychologists continue to grow, there are no sufficiently reliable measures of loss of cortical function due to brain tissue damage which are entirely foolproof. In any event, there is some doubt as to whether the demonstration of organic damage alone is of key relevance. Behavior patterns, whether they emerge in life or in tests, cannot be strictly interpreted in terms of damage to specific brain areas. The basic defenses of the individual—which may appear neurotic, regressive, psychosomatic, or psychotic—may obscure the organic lesion. Nevertheless, the physician should be sufficiently acquainted with the strengths and limitations of the most useful tests, even though he may not administer them himself, for test findings may help to highlight the patient's personality assets and defects, and so provide valuable data in planning therapy.

Suggested Cross References

More detailed information regarding methods of psychiatric and psychological examination may be found in Area E, which deals with psychiatric assessment. The reader is especially referred to Sands' section on the mental status examination (Section 11.2), Linn's section on psychiatric symptoms (Section 13.1), and Benton's section on psychological tests for organic brain damage (Section 12.2). Neuropathology and the neurological examination are discussed in Chapter 10, on neurology. Some of the specific syndromes mentioned in this section, such as epilepsy, Korsakoff's psychosis, delirium and hysteria, are discussed in different contexts in the section on epilepsy (Section 21.1), alcoholism (Section 27.3), delirium (Section 18.3), and conversion reactions (Section 23.2). Information regarding fundamental concepts of neuroanatomy and neurophysiology may be found in Sections 2.5 to 2.9 in Area B, on the basic behavioral sciences. Sharoff's section on narcotherapy (Section 35.4) in the chapter on organic treatment contains a more detailed discussion of the use of the Pentothal interview in traumatic neurosis.

20.2 BRAIN SYNDROMES ASSOCIATED WITH DRUG OR POISON INTOXICATION

EBBE CURTIS HOFF, M.D., PH.D.

Toxic psychoses may be caused by the ingestion or inhalation of or continuous contact with a wide variety of substances. In fact, most agents acting on the central nervous system may, under certain circumstances, produce inappropriate and disturbed behavior. Bromides, barbiturates, belladonna alkaloids, sulfonamides, penicillin, sympathomimetic amines, and

disulfiram are known to cause toxic effects—both neurological and psychological. The same is true of general anesthetics, certain hormones, various gases and vapors, industrial chemicals, and heavy metals. These substances constitute industrial and therapeutic hazards, and problems of dependency may be encountered with many of them. The substances to be considered here may be differentiated from a group of drugs, including mescaline, marihuana, lysergic acid diethylamide (LSD), and psilocybin, that may be responsible for profound and unusual mental states with relatively no disorientation or delirium and minimal disturbances in neurological function.

In general, the mental symptoms associated with misuse of various drugs and medications or related to metabolic disorders, nutritional deficiencies, or infections are not in themselves specific to a particular chemical substance. But the symptoms do differ, and the different potentially toxic agents vary in their potency in generating psychotic states. The abnormal behavioral responses depend not only on the toxic agent but also on quantitative, temporal, and other conditions under which the person is subjected to the agent. Personality, past experience, age, and other attributes of the individual as well as the intensity, duration, and type of the intoxication are significant factors in determination of the clinical picture.

The acute toxic psychotic reactions are characterized essentially by mental clouding and a confused state; other symptomatic components may or may not be present in a given case. Clouding of consciousness is variable, and attention may be poorly sustained. Concentration may be difficult, and the field of attention may be narrowed. The patient may tire readily and sink back into confusion. There may be growing disorientation for time, place, and person. Memory impairment may be present, especially for recent events. The patient may be restless, and this may vary from tremor to highly purposive and coordinated movements, for example, driving imaginary cars or fighting imaginary enemies. The patient may be unusually suggestible and responsive, and this may be associated with confabulation. Hallucinations, when they occur, are primarily visual, especially in the acute intoxications. There is commonly misinterpretation of actual objects. Auditory hallucinations are less common and may appear after gross confusion has disappeared. Paranoid attitudes and delusional ideas are typically transient and poorly systematized.

In summary, in the full blown, acute organic brain syndrome, one sees a restless, suggestible, confused patient in a clouded state with a high frequency of visual hallucinations and paranoid tendencies and ideas. The mood is labile, and the person may be predominantly irritable, anxious, fearful, and depressed. Sometimes the mental disturbance may be chiefly or solely confined to the nighttime and associated with bad dreams and nightmares.

The chronic toxic reactions are essentially charac-

terized by intellectual deterioration, with impairment of orientation and disturbance of both remote and recent memory. There may be various types of abnormal emotional reactions.

The diagnosis of toxic psychoses depends on a reliable history, making full use of information from relatives as well as the patient himself. Emphasis must be placed on a careful psychiatric evaluation, physical examination, and appropriate laboratory studies. The possibility of the toxic effects of drugs and other chemicals must be kept in mind in any unexplained confusional state and a careful search made for such causes.

In a toxic psychosis there may be a fatal issue, sometimes unexpected. This may be the case in physical prostration resulting from great restlessness and excitement. There is also the risk of suicide in these patients.

Treatment, in general, rests on a number of therapeutic objectives. Appropriate attention must be given to the underlying chemical agent. With some toxic substances, withdrawal may be abrupt, with symptomatic support and treatment of symptoms by other and less toxic sedatives and tranquilizers. In the case of such toxic agents as barbiturates, a carefully planned, gradual withdrawal is necessary. If misuse of a potentially toxic agent is diagnosed early enough, psychotic reactions may be prevented.

Skillful nursing care and management in a protective hospital setting are essential. Due attention must be given to the idiosyncrasies and susceptibilities of the individual patient. With competent nursing and appropriate medication, patients can be soothed and quieted. They should be kept in a quiet, evenly lighted environment with minimal danger of misinterpretation of objects. Constant reassurance, preferably from the same familiar nurse, is important.

Adequate nourishment and fluid intake, if necessary by tube feeding and intravenous fluids, must be provided. To intravenous fluids may be added 2 cc. of vitamin B complex, 100 mg. of thiamine hydrochloride, and 100 mg. of sodium ascorbate. As the patient improves, this may be followed by 100 mg. of ascorbic acid by mouth every day plus a multivitamin capsule orally each day and a daily intramuscular injection of 1 cc. of vitamin B complex. Parenteral sedatives are given as needed and indicated.

In general, use of sedation should be conservative, and barbiturates are generally to be avoided, as is paraldehyde in most cases. For hallucinating patients, 50 mg. of promazine may be given intramuscularly every 3 hours or 50 to 100 mg. of chlorpromazine, intramuscularly every 3 hours, or 20 to 40 mg. of trifluorpromazine, intramuscularly every 4 hours, provided circulatory collapse is not impending. Blood pressure, pulse, and respiration should be checked every 30 minutes in the acute patient and complications treated. Chlordiazepoxide has been used successfully in

the management of delirium tremens, and it has been found to act effectively when 100 mg. are given intramuscularly, immediately followed by 50 mg. four times a day by mouth. Sometimes, larger doses are required. In the treatment of delirium tremens with chlordiazepoxide, it has been found that, although hallucinations may persist in some cases, they are much less terrifying and more tolerable with the drug. If circulatory collapse is threatened, plasma expanders or parenteral fluids should be given. As needed, 10 mg. of metaraminol bitartrate, intramuscularly every 3 hours, may be administered; or 4 cc. of levarterenol bitartrate in saline, intravenously, 30 drops per minute, may be given. Serial electrocardiograms should be taken. If respiratory depression supervenes, 0.375 gm. of nikethamide should be given intramuscularly or subcutaneously, every 2 hours as needed or 20 mg. of methylphenidate hydrochloride, intramuscularly, every 4 hours as required.

As the patient recovers from the psychotic reaction, it is important to make long term plans for total rehabilitation insofar as this may be possible. Such planning includes medical and psychological therapy for residuals and sequelae of the acute psychotic reaction. An assessment to identify the factors underlying and leading up to the toxic psychosis must also be undertaken for preventive and rehabilitative intervention.

Bromides

The psychoses due to bromide intoxication may be cited as a model in a discussion of the toxic psychoses, since the mental aberrations caused by the misuse of bromides are the best understood among the various intoxications causing behavioral disturbances. This is partly because reliable quantitative serum bromide tests have been available for a long time and a large and complete literature has been developed on the bromide psychoses.

Incidence. Levin has expressed the conviction that the method of reporting drug psychoses in mental hospitals tends to minimize the importance of mental derangement due to bromides. He has criticized reported figures on the admissions of patients to mental hospitals for psychoses due to drugs or other exogenous poisons. Malzberg reported that psychoses due to drugs or other poisons represented very few first admissions to hospitals for mental disease in New York State. Such psychoses averaged only about 0.2 per cent of all initial admissions. Psychoses due to drugs were described as being more frequent among females than males. Moore et al. reported that 841 cases out of 115,845 admissions to Massachusetts Mental Hospitals from 1917 to 1937 were associated with excessive use of drugs. Among these 841 cases, the order of frequency of involvement was: opium derivatives, 363 cases; barbiturates, 208; bromides, 101; other sedatives, 27; analgesics, 15; gases, 19; and metals, 18. There were 54 miscellaneous cases and 36 not veri-

fied. In terms of all admissions, patients admitted because of bromides represented 0.09 per cent. These authors have pointed out that the recovery rate of cases of mental disease due to drugs is high, and the death rate is low. The immediate prognosis in mental illness due to drugs is more favorable than in all other types of acute mental disorder. Levin, in criticism of Malzberg's report, has given a figure of 3.3 per cent of admissions as due to drugs and exogenous poisons.

Levin has raised a medicolegal issue regarding the adequacy of warnings printed on the labels of medicines containing bromides and sold over the drug counter. Against the desirability of adequate label warnings, it has been argued that the bromide psychoses are rare, and it has been asserted that, when bromides are given experimentally to human subjects, they do not produce substantial signs of intoxication, even when the serum bromide concentration attains a high level, that is, 150 mg. per 100 cc. Also, it has been claimed that, when bromides do produce a psychosis, the fault lies not with the drug but with the victim's abnormal predisposition to mental disorder.

In disagreement with these arguments, Levin has objected that the incidence of drug psychoses listed by mental hospitals does not reflect the true incidence, since most hospitals are governed by statistical policies based on the direction that cases developing a psychotic reaction from the use of drugs in the treatment of other forms of psychosis should be recorded according to the primary psychosis and not as drug psychoses. In criticizing experimental studies of the bromide tolerance in normal human subjects, Levin has raised the point that in no case was the drug given to experimental subjects for longer than 4 weeks. He thinks that a basic defect in such experiments is the failure to appreciate the fact that the patients' reaction to bromide depends not only on the level of serum concentration but also on the length of time the concentration has remained at a high level. With regard to the point that the fault is not with the drug but with the victims' abnormal predispositions, Levin has asserted that it is precisely those members of the public with abnormal predisposition who, because of nervousness, are the largest consumers of bromides and who, therefore, require protection from dangerous uses of the drug. He has stressed the need for routine study of serum bromide level in all patients admitted with acute psychoses. Since bromide psychoses can easily be overlooked, the test should not be delayed. A high serum bromide level does not always mean that a bromide psychosis will supervene, but this information will alert the physician.

Acute bromide intoxication. This condition tends to be unusual, since quantities of this drug large enough to raise the blood bromide level to a toxic stage can scarcely be taken by mouth and retained

without emesis. Although acute fatalities from bromides appear to be extremely rare, there are reports in which death has been ascribed to the ingestion of a single, large dose of bromide or the taking of large amounts over a period of days. For example, an early case was described of a female patient who was found comatose and irrational after taking approximately 85 grains of potassium bromide every 4 hours for 4 days. Other cases have been described of acute poisoning by bromides, with recovery, in which the principal symptoms were depression with lethargy, confusion, weakness, and ataxia or psychosis with delirium and hallucinations. Disturbances of equilibrium with staggering gait, loss of memory, and indifference to the surroundings have also been reported. These cases are sometimes complicated by incontinence and difficulty of speech.

An experimental study of the symptoms of bromism based on self-observations has been reported by Schabelitz. He remained for 2 weeks on a low salt diet and then took daily amounts of 5 gm. of sodium bromide in single doses for 22 consecutive days. One hour after the first dose, he complained of irritability and numbness of the head, staggering gait, and a feeling of intoxication, which abated after 3 hours. From the beginning of the study, there were variations of mood, euphoria alternating with irritability.

Chronic bromide intoxication. The fact that the continued use of bromides involves the possibility of accumulation in the body and chronic poisoning is not always fully appreciated. Bromides are not invariably as safe and mild as they have traditionally been supposed to be.

Levin has pointed out that the bromide psychoses are not all similar, and he has listed four varieties: simple bromide intoxication, delirium, hallucinosis, and transitory schizophrenia associated with paranoid symptomatology. He has warned against regarding bromide psychosis, bromide intoxication, and bromide delirium as synonymous. The patient may have bromide intoxication without becoming psychotic and may exhibit a bromide psychosis without being delirious.

Simple bromide intoxication. This condition is characterized by progressive dullness, sluggishness, forgetfulness, and irritability as the bromide accumulates in the nervous system. The pupils are irregular and may become sluggish and even fixed to light. There are tremors, unsteadiness of gait, and general incoordination, and there may be slowing of speech. However, the patient remains oriented and rational. Should the intoxication be permitted to persist, the patient may become a victim of one or more of the three other varieties, and of these, delirium is the most significant.

Delirium. In a study of 100 patients suffering from bromide intoxication, Moore et al. found that the most common psychotic manifestation was delirium, which was observed in 66 per cent of the pa-

tients. According to these authors, bromide intoxication is most frequently seen in the 40 to 60 age group; 64 per cent of all the cases studied were women, and 36 per cent men. Among the 100 patients reported, 63 per cent had taken bromides on medical prescription, self-medication accounted for 22 per cent, and 15 per cent gave no adequate information. In this study, the bromides played a subordinate role in suicidal attempts. The duration of use of the drug varied; in the majority of the cases, it had not been longer than 3 months. The characteristic manifestation of bromide delirium is disorientation. The patient may suffer for some weeks with a simple intoxication and then may become confused as to time. There may be disturbances of mood, restlessness, apprehensiveness, inability to sleep, delusions, and hallucinations.

Transitory schizophrenia. Bromide intoxication is one of the toxic conditions that can bring about a transitory schizophrenia. This bromide schizophrenia is associated with paranoid symptomatology. The patient, usually a female, is typically one with a schizoid personality who has taken bromides for some neurotic symptom and after a time becomes dull and shows other signs of simple intoxication.

The distinction between this and other schizophrenic reactions may be made on the basis of the clinical course. In bromide schizophrenia there is a relatively acute onset in the course of a bromide intoxication, and this clears up some weeks or months after the drug has been withdrawn. There may or may not be disorientation. That is to say, there may be an admixture of delirium. Bromide schizophrenia, however, is to be differentiated from delirium and from hallucinosis. Continuing to take bromides, the patient begins to have ideas of reference, delusions, and hallucinations of the type seen in paranoid schizophrenia. In this type of bromide psychosis, there are disturbances of rapport and affectivity that characterize schizophrenia in general. The patient is aloof, withdrawn, suspicious, and negativistic. By contrast, delirious patients without schizophrenia, however confused they may be, are in good rapport. They are usually friendly and accessible and, far from being withdrawn, cling to the nurse or physician and beg for protection. The delirious patient tends to confuse the unfamiliar with the familiar. For example, he may mistake the nurse for his wife, and his mistakes are not bizarre. In bromide schizophrenia, however, when disorientation is present, it tends to have an outlandish nature. Moreover, self-reference is tremendously increased in bromide schizophrenia. In bromide delirium, there may be many fears of disaster, but the patient does not seem to be singled out as the sole victim; rather, he sees himself as one of many who are threatened. Thus, he remains a socially oriented person, not isolated from others. In bromide schizophrenia, however, the patient conceives himself to be alone in the danger and isolated.

Hallucinosi. Bromide hallucinosis is to be differentiated from delirium by the fact that the patient remains well oriented in spite of his hallucinations.

Signs and symptoms. The most prominent manifestations of chronic bromide intoxication are neurological and mental disturbances, and these comprise the most grave aspects of the condition. The symptoms have been listed in the following order of diminishing frequency: headache, irritability, emotional instability, weakness, lethargy, slurring speech, irrelevant speech, delusions, disorientation, hallucinations, loss of memory, cyanosis, vacuous facies, dilated pupils, stupor, blurred vision, fabrication, ataxia, mental confusion, disordered dreams, vertigo, and loss of libido. These symptoms may develop slowly, and it is generally agreed that disturbed mental states do not usually appear until the blood bromide concentration reaches or exceeds 150 mg. per 100 cc. There are, however, disputes as to the toxic level of bromide, and many patients become delirious before this level is attained. The level alone is not critical but must be considered in terms of the duration over which the drug has been taken and the elapsed period of withdrawal from the drug.

The signs and symptoms vary greatly from one patient to another and are highly dependent on individual personality and metabolic factors. Bromide intoxication may simulate a number of neurological or mental diseases and may be complicated by these conditions. The presenting state may be that of coma, or the patient may be stuporous, drowsy, depressed, or confused. In severe cases, delirium, delusions, auditory or visual hallucinations, or other acute psychotic symptoms become predominant and severe. Weakness, sluggishness of movement, motor incoordination, faulty gait, ataxia, and reflex disturbances are prominent features of chronic bromism. Visual disturbances include diplopia, blurred vision, disturbance of color vision, and photophobia. The pupils may be dilated, unequal, or irregular.

Since bromism may simulate or be mistaken for a number of neurological disorders, a suspicion that drug intoxication is present should always be entertained in making the diagnosis of any unusual nervous or mental condition. If there is a doubt as to the diagnosis, blood bromide and chloride levels should be examined. As Levin has stated, such patients may be admitted to the hospital in a low muttering delirium, lying quietly in bed without making any disturbance. On the 3rd or 4th day after withdrawal of the drug, the patient may become terrified and violent. Levin has pointed out that the pitfall is the assumption that the frenzy is a bad sign. On the contrary, he feels that it is a good sign. On admission, the patient was helpless and almost comatose, but as the neurological recovery proceeds and as restitution is on the way, differential return of function in different brain areas may account for the hyperactive behavior.

In a number of cases of chronic bromide intoxication, there seems to be a special idiosyncrasy to the drug. The duration of taking of the drug in intoxication cases varies. In a majority this has not been longer than 3 months. It has been emphasized that bromide acne is the most pathognomonic criterion in the diagnosis of bromide intoxication. However, it should be made clear that acne is frequently absent in intoxication with very high blood bromide levels. Moreover, bromide acne may be present in cases with quite low bromide levels. Attention should also be drawn to the variability of the neurological manifestations and to the fact that these are often obscured by preexisting conditions not associated with bromide intoxication. After discontinuation of the bromides, the average duration of intoxication has been estimated as between 2 and 6 weeks.

Levin's criticisms of a report by Millikan and Paul require presentation. The latter authors administered varying doses of sodium bromide to 36 hospital patients over prolonged periods of time. Eleven of the patients developed bromide intoxication, characterized by increased desire for sleep, dulling of higher mental functions, slurred speech, unsteady gait, and clouding of consciousness. The lowest blood bromide level at which any patient developed intoxication was 195 mg. per 100 cc. Eight patients showed evidence of intoxication between 200 and 300 mg. per 100 cc. One patient exhibited toxic signs at 319 mg. per cc. Toxic symptoms in nine patients included delusions, hallucinations, and disorientation. Signs such as crying, excitement, and confabulation developed secondarily. All patients who were made psychotic by the ingestion of sodium bromide were either suffering from a psychoneurosis or were described as psychopaths. Millikan and Paul asserted that they were unable to produce this syndrome in any patient having a stable personality. It was in criticism of these findings that Levin emphasized the importance of long continued high levels of serum bromide as an essential factor in bromide delirium.

Levin's criticism has also extended to reports by Jellinek et al. These investigators achieved serum bromide levels averaging 142 mg. per 100 cc. in the course of 4 weeks of bromization in 78 normal subjects through the administration of daily doses of 50 mg. of sodium bromide per kilogram of body weight. From time to time the dosage was adjusted to assure blood levels between 100 and 200 mg. per 100 cc. In 20 psychotic patients a mean bromide level of 134 mg. per 100 cc. was reached after 6 weeks of medication. It was reported that the normal subjects showed no symptoms of either bromide psychosis or intoxication but only the effects of sedation, manifested for the most part in deeper sleep and in some defects of concentration considered due to relaxation brought about by sedation. Of the 20 psychotic patients, only 2 gave evidence of mild intoxication; the others revealed only sedation and even some clinical improvement. It was admitted that the psychotic subjects may have been somewhat more susceptible to bromide effects than normal subjects. A group of 28 psychotic patients was given 75 to 100 mg. of sodium bromide per kilogram of body weight daily for 6 to 8 weeks. These patients reached a mean serum bromide level of 228 mg. per 100 cc., with a maximum of 310 mg. Of this group, 57 per cent of the patients revealed some evidence of bromide intoxication, such as decreased reflex activity, loss of pupillary reaction to light, and extreme drowsiness. It was reported, however, that there was no considerable increase in the psychotic symptoms. Jellinek et al. concluded that normal individuals are not likely to develop toxic symptoms at serum bromide levels between 100 and 200 mg. per 100 cc. and that mental hospital patients with long hospitalization are only slightly

more susceptible to bromide effects at comparable levels. At bromide levels between 200 and 300 mg. per 100 cc., however, mental patients of the same type showed definite signs of intoxication but little if any exacerbation of their psychotic symptoms. Levin believed that Jellinek et al. overlooked the fact of duration at a given serum bromide level and considered that these studies may cast doubt on or minimize the fact that bromides can cause mental derangement.

As has been stated by Goodman and Gilman, there appears to be no absolute correlation between the severity of bromide poisoning and the level of bromide in the blood, and many factors are concerned in determining whether a patient with a given blood bromide level will show evidence of intoxication. Among these undoubtedly are the physical and mental condition of the patient; the food and salt intake; and the presence or absence of dehydration, vomiting, diarrhea, and impaired renal function. Goodman and Gilman have pointed out, for example, that a patient who is cachectic, dehydrated, and on a poor chloride intake may exhibit severe symptoms of bromide intoxication when the blood bromide level is only 100 mg. per 100 cc., that is, when only 12.5 per cent of the blood chlorides have been replaced by bromide. Again, epileptic patients may continuously have blood bromide levels of 100 to 150 mg. per 100 cc. with only mild sedation. Goodman and Gilman, however, have placed the definitely toxic zone at blood bromide levels of 150 to 200 mg. per 100 cc. and have asserted that most patients with the latter concentration will show unmistakable evidence of poisoning. The literature is replete with case histories in which severe mental symptoms have been reported with blood bromide levels of this magnitude. Goodman and Gilman have also stressed the fact that the urinary content of bromides does *not* present a reliable guide in the detection of bromide intoxication.

Published case reports of bromide poisoning with mental symptoms show that the earliest symptoms of bromide intoxication are fatigue and sleepiness, with gradually increasing ataxia. Early signs of cardiac involvement (weakness and irregularity of the pulse) are frequent, and severe disturbances of heart action may occur. There may be poor appetite, severe constipation, loss of weight, and cachexia. Broken sleep occurs as an early sign. A relatively small number of patients suffering from bromide intoxication develop delirium, characterized by clouding of consciousness, disorientation, difficulty of comprehension, exaggerated fears, and dreamlike hallucinations, predominantly visual, in which colors, lights, and large animals are frequently reported. The duration is from 10 days to 2 weeks, unless constitutional factors, such as manic or depressive components, exert a dominant influence. Diethelm has stated that bromide delirium occurs more frequently in the United States than in Europe, probably because the lower chloride content in American food does not offer sufficient balance to the bromides. He

stressed the fact that chronic intoxication and delirium occur easily in patients with cardiorenal disorders and structural brain involvement, as in cerebral arteriosclerosis. Chronic alcoholics probably have a lower resistance because of cardiorenal and cerebral damage. Epileptics may have a phenomenal resistance to bromides. Diethelm cited the case of one epileptic patient who had a blood bromide level of over 400 mg. per 100 cc. without showing more than sluggishness and ataxia. Such a level is ordinarily incompatible with life for any length of time.

Treatment. Adequate treatment of bromide intoxication can be undertaken only after a definite diagnosis has been made. Determination of bromide poisoning utilizes clinical evaluation as well as investigation of blood bromide and chloride levels. Treatment of bromide intoxication also includes careful investigation of and therapy for the underlying condition for which the patient originally took the bromides. All possible sources of bromide intake should be withdrawn at once and treatment undertaken to effect the elimination of bromide from the body as quickly as possible. Psychological and neurological as well as other symptoms should receive attention as indicated. The use of other sedatives is generally contraindicated, but measures may be required to quiet disturbed or delirious patients.

It has been suggested that paraldehyde is the drug of choice in sedation of these patients; 15 cc. of paraldehyde may be given every 4 to 6 hours by mouth or 4 cc., intramuscularly, in each buttock every 6 hours. In some psychiatric services, paraldehyde is not administered intramuscularly because of the possibility of local necrosis. Chlorpromazine may be given intramuscularly, 50 mg., every 4 hours.

Although measures to speed excretion of bromide are recommended, there is no indication that they will necessarily hasten recovery. There is commonly a definite lag in the onset of psychotic symptoms and their resolution in comparison with the rise and fall of the blood bromide level. Thus, while the drug is accumulating in the blood, delirium may not set in until a level of 300 mg. has been reached, but it may persist after the level has dropped to as low as 75 mg. per 100 cc. This supports the view that the serum bromide determination gives only a partial account of the actual status of the nerve cells bathed in the cerebrospinal fluid.

Elimination of bromide is hastened by administration of sodium chloride. This is given by mouth or by the intravenous infusion of physiological saline. The total daily therapeutic amount of sodium chloride varies from 6 to 12 gm., given in divided doses over and above the salt contained in the diet. It is important that a high fluid intake be maintained to insure diuresis and to prevent loss of body water as a result of the large doses of salt. Adequate food intake, if necessary by gavage, is necessary to combat

malnutrition, which may often complicate chronic bromide poisoning.

The value of niacinamide in the treatment of bromide intoxication has been recommended. Studies of human patients and volunteers have also shown that bromide is excreted and symptoms are relieved more rapidly with ammonium chloride than with sodium chloride treatment alone. The reasoning behind this is that ammonium chloride, aside from adding chloride, also acts as a diuretic. The use of mercurial diuretics in the treatment of bromide intoxication has also been investigated as a means of overcoming poor success with some patients in reducing the bromide level by chloride administration alone. In treating cases of chronic bromide poisoning with 6 gm. of sodium chloride added to the daily diet, 2 cc. of the mercurial diuretic meralluride (Mercuryhydrin) are injected intramuscularly at intervals of 2 or 3 days. Clinical studies have shown that Mercuryhydrin increases the excretion of bromide both by promoting urinary output and by raising the bromide concentration in the urine. This drug has been recommended for use with either sodium chloride or ammonium chloride. Subcoma insulin has also been used to aid elimination of the bromides.

Adrenal cortical extract may be administered in conjunction with sodium chloride. The combination of sodium chloride and deoxycorticosterone has also been used. Patients treated with this combination have been found to improve more rapidly than those given sodium chloride alone. On this treatment regimen the recovery time has been found to be between 10 and 24 days. The time necessary for the reduction of blood bromide by 50 per cent varies between 8.5 and 14.5 days for patients treated with salt alone and between 4 and 8 days for patients treated with deoxycorticosterone as well as salt. In general, it has been found that recovery requires from 1 to 3 or more weeks when chloride is administered adequately. As indicated, it is found that, as the blood bromide concentration falls, symptoms of intoxication disappear at a bromide level that is usually lower than that at which they originally made their appearance.

Barbiturates

Symptoms. Mild, simple intoxication with barbiturates results in acute and chronic symptoms somewhat similar to those observed in alcohol intoxication. There is dullness, sluggishness, sleepiness, slowness of speech and understanding, impaired memory, and disturbances in thought processes and judgment. Patients exhibit a narrowing of the range of their attention and may be emotionally labile, exhibiting querulousness, petulance, and irritability. They may be morose and hostile and show paranoid ideation. Inappropriate emotional behavior is common, and the victim may laugh or cry irrelevantly. It is characteristic for them to become untidy and

careless of their appearance, work, and habits. The patients make mistakes in meticulous tasks requiring precise attention and concentration. Neurological manifestations include slurring of speech, nystagmus, diplopia, strabismus, faulty accommodation, vertigo, ataxia, disturbances of muscle tone, and decrease in superficial reflexes.

Treatment. Following acute barbiturate poisoning, there may be confusion and more serious psychotic manifestations. Protection and continued nursing care are essential, and sedation may be given in the form of small amounts of paraldehyde to induce sleep. Treatment may be required for pulmonary disturbances resulting from inhalation of liquid or semiliquid foods. Subsequent psychiatric evaluation and appropriate treatment (as of attempted suicide) is mandatory.

In barbiturate addiction, psychotic disturbances may occur between the 4th and 7th day following withdrawal. Hallucinations are predominantly visual but may be auditory as well. Delirium is apt to be worse at night, and the patient is likely to be disoriented as to time and space but not as to person. The psychosis usually terminates abruptly after 3 to 5 days and is succeeded by sleep for 8 to 12 hours. There is partial memory of hallucinatory material. During delirium the body temperature is usually elevated 1.8 to 3.6° F. A rapidly rising temperature is an ominous sign and may indicate a fatal termination. Also, if delirium has developed during withdrawal from chronic barbiturate intake, prognosis must be guarded, since this condition is occasionally fatal.

Abrupt withdrawal of barbiturates from addicted persons is absolutely contraindicated. The patient should be hospitalized where control of the environment can be effectively achieved. If a diagnosis of barbiturate addiction can be made before objective signs of withdrawal appear, the patient should be given pentobarbital in amounts sufficient to maintain a state of mild barbiturate intoxication. Usually 0.2 to 0.3 gm. of pentobarbital every 6 hours until all necessary examinations have been completed is sufficient. After this, a gradual withdrawal is accomplished by reducing the daily administration by no more than 0.1 gm. If symptoms appear, the reduction is discontinued until they abate. Withdrawal is usually accomplished within 14 to 21 days. If barbiturate addiction is diagnosed after a major convulsion or after psychosis has appeared, the patient should immediately be given 0.3 to 0.5 gm. of pentobarbital either orally or parenterally. Then barbiturates are administered every 4 to 6 hours in amounts sufficient to cause a mild intoxication. After re intoxication with barbiturates has been achieved, gradual withdrawal is carried out. When withdrawal is complete, psychiatric evaluation and appropriate psychotherapeutic planning are necessary.

Withdrawal may sometimes better be accomplished

by reducing the dosage every other day. Convulsions can be prevented by giving 100 mg. of diphenylhydantoin (Dilantin) three times a day by mouth for 2 weeks.

Withdrawal effects. Delirium and other psychotic manifestations may supervene after withdrawal of barbiturates, and cases have also been observed in which delirium began even while the patient was presumably taking the drug. In patients who have become dependent on barbiturates, withdrawal may be characterized by tremulousness, asthenia, anxiety, and inability to sleep. Mild withdrawal effects may be limited to paroxysmal abnormalities in the electroencephalogram (EEG), but in severe cases there may be grand mal seizures.

Studies by Fraser et al. have shown that a daily dose of 0.4 gm. of pentobarbital for 3 months is a precondition for abrupt withdrawal effects characterized by paroxysmal EEG changes alone. In subjects withdrawn after 1 to 2 months on 0.6 gm. per day, one half exhibited minor symptoms, such as tremor, loss of appetite, and insomnia; seizures occurred in some. However, in subjects given 0.9 to 2.2 gm. per day for a number of months, three quarters experienced seizures, and approximately two thirds became delirious. Sleepiness, tremor, and loss of appetite were seen in all these subjects.

The anxiety, tremulousness, and weakness following withdrawal of short-acting barbiturates occurs within the first 12 to 16 hours, and the symptoms may become maximal during the 2nd or 3rd day, during which time seizures are most common if they occur at all. With the longer-acting barbiturates, the maximal period for most intense withdrawal symptoms is later. As is the case with withdrawal from alcohol, delirium may develop after 2 or 3 days. The patients are anxious and plagued by horrifying dreams and inability to sleep. The hallucinatory material is usually visual, as with alcohol delirium tremens, and the patient experiences the sense of being persecuted or attacked. He may be disoriented, agitated, and exhausted. Delirium, if it occurs, is most common between the 4th and 7th day after withdrawal and ordinarily subsides by the 8th to 10th day, even without therapeutic intervention, and the patient is left depleted and sleepy. As with delirium caused by withdrawal from alcohol, hallucinations may continue for many weeks or months, in which case the diagnosis of an underlying psychotic condition should be explored.

Amphetamines

Amphetamines are commonly prescribed in the treatment of overweight patients and as mild antidepressants, and, although they do cause an enhanced sense of well being, addiction to these drugs is apparently not common. A psychotic reaction may occur after a single excessive dose (say 55 to 75 mg. of dextroamphetamine). Manifestations may occur in 36 to 48 hours and may be extremely difficult to dif-

ferentiate from a schizophrenic reaction. There are characteristically excitement, auditory and visual hallucinations, paranoid thinking, and looseness of logical associations between successive items in the stream of talk. The sensorium remains clear. Unless the drug is continued, the condition is usually limited to about 7 days. Continued overuse of the amphetamines for many weeks or months may also result in a toxic psychosis.

In a report on psychoses due to amphetamine consumption, Beamish and Kiloh have described case histories supporting the point that, in the majority of cases of psychotic illness occurring in association with amphetamine consumption, the picture resembles that of paranoid schizophrenia. Without an accurate knowledge of the drug intake, it is easy to misdiagnose the condition as a schizophrenia. Beamish and Kiloh have also pointed out that the psychotic symptoms usually disappear within a few days of drug withdrawal, responding quickly to hospitalization, no matter what the treatment. In the majority of cases, withdrawal is without danger. In one of the cases reported by Beamish and Kiloh, delirium occurred as a withdrawal phenomenon, but in this case barbiturates may have complicated the situation.

In amphetamine psychosis, 25 to 50 mg. of chlorpromazine may be given intramuscularly every 4 hours for sedation.

In general, the therapy of amphetamine intoxication is entirely symptomatic. The patient should be hospitalized, reassured, protected, and sustained in a quiet, constant environment. As stated, the psychotic symptoms usually clear rapidly after discontinuance; abrupt withdrawal causes no major observable physiological disruptions that would require gradual reduction of the drug. Clearance of amphetamine is usually accomplished within a week. In some cases, gradual withdrawal of the drug may be desirable.

A male patient began to take benzedrine as a college student. Several years later, he was admitted to a mental hospital with a diagnosis of paranoid schizophrenia. He continued to obtain amphetamine while in the hospital and showed wide mood swings. After several hospital admissions, the patient was treated with a prefrontal lobotomy. After this intervention, the patient continued to take amphetamines.

A 23-year-old man complained of cramplike pain over the precordium, a tingling sensation over the face, and difficulty in breathing. The symptoms were of 5 hours' duration, and the patient had been using a benzedrine inhaler to relieve nasal obstruction over a period of 18 hours prior to the onset of symptoms. His respiration was shallow and rapid, he was sweating profusely, and his pupils were dilated but reacted to light and accommodation. The pulse was 140 per minute, the blood pressure was 200/100 mm. Hg, and the blood glucose was 125 mg. per cent. There were signs of confusion and tachypnea (50 per minute). Tachycardia (160 per minute) developed, and there were auditory hallucinations. Treatment with 10 cc. of paraldehyde by mouth twice quieted him, and the symptoms disappeared. It was estimated that about 265 mg. of benzedrine had been taken into his body.

A 32-year-old woman ingested 200 mg. of dextroamphetamine 12 hours before examination. She was aggressive, suspicious, and restless. There was flushing, profuse sweating, and

dryness of the mouth. The symptoms cleared rapidly on sedation with paraldehyde.

Other cases of acute amphetamine poisoning have been recorded in which there were visual or auditory hallucinations, excitement, confusion, paranoid delusions, and depression. There are also cases of amphetamine poisoning in children 2 to 4 years of age who inadvertently swallow tablets containing amphetamines. In one case, a 4-year-old boy took about 70 to 90 mg. of amphetamine. He became overactive, elated, and delusional and had auditory illusions. He seemed to hear music and soft voices. The patient recovered in 10 hours after minimal sedation. Another child, two years of age, swallowed an undetermined number of tablets, each containing 2.5 mg. of amphetamine. He became very restless and talked all night, sometimes incoherently. In other such cases, the amount of amphetamine taken, when known, varied from 55 to 115 mg.

Belladonna Alkaloids

The sudden onset of bizarre psychological and neurological symptoms should always lead to the suspicion of drug toxicity, and poisoning by atropine should always be considered. Drugs of the belladonna group can cause severe delirium. Indeed, in both children and adults, toxic effects can be induced even in such small doses as are used by conjunctival instillation to dilate the pupils. Toxic sequelae of serious proportions have resulted from using atropine or scopolamine instead of homatropine in eye drops.

The psychotic manifestations of overdose of atropine may be observed with doses of 10 mg. and more and are associated with burning and dryness of the mouth, difficulty in deglutition and speech, and intense thirst. The pupils are widely dilated, with blurring of vision and sensitivity to light. The skin is hot, dry, and flushed and sometimes exhibits a rash. Alarming hyperexia (over 109° F.) may complicate the situation. In addition to weakness, nausea, vomiting, and other manifestations, there are acute disturbances of the sensorium, with clouding of the memory and faulty orientation. The hallucinations are particularly visual.

It is possible to confuse atropine psychosis for an acute schizophrenic reaction. Signs of paralysis of parasympathetic end effects should be sought, that is, dry mouth, wide dilatation of the pupils, hyperthermia, and racing heart. Dameshek and Feinsilver have suggested administration hypodermically of 10 to 30 mg. of methacholine as a diagnostic procedure in doubtful cases, since atropine abolishes the sweating, lacrimation, salivation, and nasal discharge that are typical effects of methacholine.

When the drug has been taken by mouth, victims of atropine poisoning must be treated without delay by measures to limit absorption of the drug into the blood stream. If sedatives are used to allay excitement, these should not be given in large doses, since central nervous system depression, which may occur later, may thus be potentiated by the sedatives.

Mundy and Zeller have reported the successful treatment of a case of scopolamine psychosis with chlorpromazine. Chlorpromazine may be given in amounts up to 800 mg. daily. It is suggested that

one half of the dose be given orally and one half intramuscularly. As the patient improves, the intramuscular dose may be discontinued, and 50 mg. may be given orally every 4 hours as necessary.

Thiocyanates

Sodium thiocyanate and potassium thiocyanate have been used in the treatment of hypertension. However, there is a high incidence of toxic reactions, even at blood levels as low as 8 to 12 mg. per cent. There is accumulation of thiocyanates in the body, even when the dosage is stabilized, especially when the intake of sodium chloride has been limited. The toxic effects include sleepiness, asthenia, irritability, confusion, hallucinations, and delirium. Since thiocyanate is sometimes still used in the treatment of high blood pressure, a thiocyanate psychosis may be mistaken for hypertensive encephalopathy. The determination of a thiocyanate blood level establishes the diagnosis. Measures should be taken to accelerate the clearance of the substance from the body by administration of large amounts of chloride.

Cases of recurrent thiocyanate psychosis have been reported. In one case, the psychosis cleared within 7 to 14 days of each admission to the hospital, without specific therapy. This patient had been taking potassium thiocyanate for 10 years. She had used more than the prescribed dosage when she felt badly and had a blood level of 36 mg. per cent on her most recent admission. This was reduced to 15 mg. per cent on the 9th day of hospitalization. Clinical improvement paralleled the removal of the thiocyanate.

Another patient became disoriented and had paranoid delusions 2 weeks after taking 0.22 gm. of sodium thiocyanate three times daily. On the 2nd day of hospitalization, the patient was less agitated, and the serum thiocyanate level was 19.7 mg. per cent. She became less responsive, however, and the deterioration of her clinical state prompted the use of extracorporeal hemodialysis on the 3rd hospital day. Dialysis was continued for 5 hours. The serum thiocyanate level fell to 3 mg. per cent just after completion of the dialysis but rose to 7.0 mg. per cent 8 hours later. Twenty-four hours after dialysis, the patient was improved, and on the 15th day after dialysis she had returned to her normal mental state. The patient was discharged on the 27th hospital day with a serum thiocyanate of 2.1 mg. per cent.

It appears, therefore, that in urgent cases of thiocyanate psychosis, the most satisfactory procedure is hemodialysis. Sedatives may be used. It is well to point out that a survey of the recent literature reports a mortality of 37 per cent in a series of 53 cases of thiocyanate psychosis. The mechanism by which the thiocyanate ion induces the psychosis is not known. Prevention by avoiding the drug seems indicated.

Anesthetics

The volatile anesthetics are inert in the body and rapidly excreted. Toxic psychotic reactions in patients who have undergone surgery under the influence of volatile anesthetics are due to incidental causes associated with the operative procedure in which there is for one reason or another a faulty

transport of oxygen to the tissues. The disturbance, therefore, is essentially the result of central nervous system hypoxia.

Nitrous oxide can cause cerebral damage with mental defect, epilepsy, and extrapyramidal syndromes. Here again, the symptoms are to be ascribed to damage caused by oxygen deficiency.

Cocaine, used locally, can result in overexcitement, delirium, and convulsions. The likelihood of such contretemps may be minimized by the use of such vasoconstrictors as epinephrine with the cocaine. Some patients are unusually sensitive to cocaine when locally injected.

Psychotic problems arising from anesthetics are very rare, and preventive measures are usually effective. Treatment consists in symptomatic therapy and in dealing with the basic causes of hypoxia.

Hormones

A certain percentage of the psychotic reactions associated with the therapeutic use of hormones may be complications of some of the diseases for which the hormones are given. For example, there is a greater than normal occurrence of psychiatric disturbances among patients with Addison's disease, Cushing's syndrome, hypothyroidism, and hyperthyroidism. Hormone administration constitutes a complicated stress, and the patient's response depends on a wide range of physiological and psychological factors and interactions modified by the stress.

In the course of therapy with adrenocortical steroids, psychoses may be grave and frequent. Treatment with cortisone and adrenocorticotrophic hormone (ACTH) commonly results in euphoria and joviality, which are consistent with continuation of these hormones. However, there are major mental disturbances that assume various forms, including hallucinations, paranoid delusions, and affective disturbances ranging from depression to hypomania. There may be apathy or panic with uncontrollable excitement. There may also be intellectual-affective dissociation, bewilderment, and depersonalization. Suicidal tendencies are common.

Some authors have not discerned any characteristics of premorbid personality that might enable one to anticipate the occurrence or predict the severity or duration of psychiatric complications. Others have drawn attention to the relationship between the patient's previous mental status and his response. It has been stated that serious reactions are more likely to be found in those patients who have a prior history of psychosis or other evidence of instability. It has been said that the psychosis with cortisone or ACTH may represent an intensification of personality disturbances that existed in the past. However, the fact that there is no history of a previous psychotic breakdown or of emotional maladjustment does not guarantee that during hormonal therapy

there will not be a psychosis. Moreover, successful tolerance of previous treatment with corticosteroids does not necessarily mean that there will be no psychotic disturbance during subsequent hormonal therapy.

There appears to be no correlation between the dose of cortisone or ACTH and the severity or duration of the psychosis. The onset of the psychosis is not regularly correlated with chemical changes occurring in the course of therapy.

The management of the psychoses associated with adrenal corticosteroids presents many problems. If the patient has an illness that threatens life, the hormone may have to be continued, even though there is a psychosis. However, the dosage should generally be reduced for several days, with continuous psychiatric observation. If the condition clears, the reduced dosage may be continued or adjustment of dosage made to the point where the patient remains psychiatrically stable and at the same time benefits from the medication. The hormone may have to be withdrawn if the patient's mental condition continues to deteriorate or does not clear. Transfer from ACTH to cortisone may sometimes correct the psychiatric problem. Hormone-induced psychosis may occur spontaneously but may endure several months. Patients with suicidal tendencies may benefit from electroshock therapy; electroshock has also terminated excited states and induced complete remission of symptoms.

In high dosage ACTH therapy for multiple sclerosis, mental changes of psychiatric or borderline psychotic proportions have been reported in approximately 16 per cent of cases. Striking reversal has been effected by changing the medication to hydrocortisone or a cortisone-equivalent drug (dexamethasone). Such reversal has been accomplished within 6 to 16 days. It has been found that patients taking ACTH without becoming mentally disturbed present a picture of sustained and gradually changing output of 17-ketosteroids and 17-hydroxycorticoids. The disturbed patients exhibit sharp and rapid fluctuations in 17-hydroxycorticoid excretion.

A case has been reported of a 56-year-old woman with advanced generalized rheumatoid arthritis who was given 4,600 mg. of ACTH intramuscularly in the course of 77 days (40 to 80 mg. per day). During the first 2 months of therapy, the patient did well, showing only a mild euphoria. She then became suspicious and agitated and within less than 2 weeks exhibited paranoid ideation. ACTH was discontinued 3 days later, at which time the patient was drowsy and depressed. She remained depressed, withdrawn, and defiant for 2 weeks, and paranoid delusions and hallucinations were present. By the end of 2 weeks, there was gradual improvement, with full recovery in the following 2 weeks. Coincident with the improvement of the mental state, there was relapse of her arthritis. She was placed on cortisone by mouth, with remission of the arthritic condition, and was discharged from the hospital on cortisone (150 mg. per day). She continued on cortisone with no recurrence of the psychiatric complications.

Disulfiram

There have been reports of acute psychotic crises in alcoholic patients using disulfiram as a deterrent measure to enforce abstinence from alcoholic beverages. This was particularly the case in the earlier years of the clinical use of disulfiram and has been ascribed to three principal causes. First, it has been held that the administration of disulfiram, with the ominous threat of a dangerous and terrifying disulfiram-alcohol reaction, built around the patient a high pharmacological fence within which he felt trapped. Second, the restrictions imposed by disulfiram, if severely reinforced by a highly restrictive therapeutic strategy and inadequate therapeutic attention to underlying psychological factors in the patient's drinking problem, have the effect of bringing these factors into prominence as overt mental disturbances. Third, one was dealing with a toxic problem associated with the unnecessarily high doses of disulfiram that were often administered.

Maintenance doses of 0.5 gm. or more per day have been given in the past, but there seems no reason to suppose that such high doses are any more effective than the safer dose of 0.25 gm. per day that seems to produce fewer symptoms. At the dose of 0.25 gm. per day, most patients show no toxic reactions whatever and may continue to take disulfiram for several years without any untoward effects. On the daily dose of 0.25 gm., there are occasionally feelings of lassitude and reduction in sexual interest and potency. These symptoms can usually be corrected quickly by reducing the daily dose to 0.125 gm. A daily maintained dose of either 0.25 or 0.125 gm. is sufficient to cause an unpleasant disulfiram-alcohol reaction. Hoff and McKeown found that, when disulfiram was introduced to the patient in the hospital by giving 4 gm. of the substance over a period of 4 days prior to the disulfiram-alcohol challenge, no acute psychotic effects were manifest in 1,020 patients. It thus appears that, if a toxic psychosis does supervene, this is referable to a long continued heavy dosage.

Apparently, disulfiram acts to alter the intermediary metabolism of alcohol, with a resulting increase in concentration of acetaldehyde in the body. This substance rapidly produces a spreading cutaneous vasodilatation, which appears to be primarily responsible for the signs and symptoms of the reaction. The disulfiram-alcohol reaction is of early onset (within 5 to 10 minutes) and is self-terminating in about an hour or two. Although exceedingly unpleasant, the reaction has never been complicated by psychotic manifestations in Hoff's experience.

Untoward complications of prolonged, daily disulfiram administration can be obviated, as stated, by keeping the daily dose within 0.25 gm. and also by encouraging the patient to monitor his own ad-

ministration of the drug so that he conceives of its use as a means of reinforcing his own motivation for sobriety and rehabilitation.

Antibiotics

Neuropsychiatric disturbances may complicate the administration of various sulfonamides. Since fevers and infections may be causative of toxic psychoses, it is not always certain whether the underlying infection or the sulfonamide or both are operating. After administration of sulfonamides, there may be drowsiness, confusion, depression, inability to sleep, terrifying dreams, acute psychotic reactions, unsteadiness of gait, ringing in the ears, and vertigo. There have been reports also of toxic psychoses following penicillin administration in a small number of cases. In patients with secondary syphilis treated with penicillin, the Jarsch-Herxheimer reaction—occurring a few hours after initial administration of penicillin and characterized by chills, fever, headaches, and muscle and joint pains—may also be accompanied by delirium and convulsions.

Gases and Vapors

Concern for the poisonous actions of gases and toxic vapors belongs primarily in the fields of industrial, aviation, submarine, diving, and space medicine. The nervous system is heavily involved in the stresses to which man may be exposed in enclosed environments above the earth, under the sea, and in special working conditions. Psychological disturbances from excessive stress in these environments are complicated and variable. Questions of tolerance and adaptation are highly important.

Oxygen

Oxygen lack. There is evidence of very strong sensitivity of the higher cerebral centers to oxygen lack. If one accepts the concept of a metabolic gradient in the central nervous system, it follows that not all parts of the brain are equally affected by hypoxia: those regions with the highest metabolic rates succumb first, and those with the lowest rates succumb last. During a slow, progressive hypoxia, precise contact with the environment is first lost. There then follows aimless motor restlessness, succeeded by muscle spasms, convulsive episodes, disturbance of heart action, and failing respiration. It has been found that lowering oxygen concentration of inspired air slows the rate of cortical potentials. The slowing is greater the lower the oxygen level. The greatest slowing occurs when both oxygen and carbon dioxide content are low.

The electroencephalograms of psychoneurotic patients tend to exhibit a greater degree of slowing than do those of normal adults, suggesting a more labile metabolic process in the brain cells of patients than in normal persons. Within a minute after breathing 6 or 7 per cent oxygen, the electroencephalo-

gram is characterized by small, rapid waves; 2 or 3 minutes later, there are slow, large δ waves appearing in groups. The mean amplitude increases rapidly, and the final stage after about 5 minutes contains almost all δ waves. Performance, as estimated by psychological tests, is progressively impaired. In comparing psychoneurotic patients with control subjects, researchers have found that the latter deteriorate more on reaction time tests, and the patients show a greater drop in the tapping speed and stylus tests. When the two groups are compared directly with each other in regard to the amount of change reproduced by hypoxia, there is no statistically significant difference between them. Regarding the appearance of physical signs of stress, both groups are much alike in type, frequency, and severity of symptoms, except that the controls seem to experience headache and giddiness more frequently, while the patients experience more difficulty in breathing and more tremor and unsteadiness.

Performance decrements due to oxygen want tend to appear quite suddenly. For example, it has been found that hypoxia does not disturb or impair simple, habitual responses until it has continued for at least an hour below 10.25 per cent without previous acclimatization. Ambient air contains 20 per cent oxygen. Kinesthesia and visual function are first affected; audition is affected later. Multiple choice reactions are impaired at oxygen levels of about 11.5 per cent, at which levels there is also deterioration of neuromuscular control, as demonstrated by loss of performance in handwriting tests. When oxygen falls as low as approximately 9 per cent, there is loss of memory and defective awareness of lapse of time.

The effects of low oxygen on higher mental processes depend to some extent on the emotional tendencies of the subject. Some individuals become lethargic or indifferent; others experience outbursts of anger. In one study of 17 medical students and 9 psychoneurotic patients exposed to 13 per cent oxygen for 3 hours, the students complained of frontal headaches, dizziness, yawning, oppressive pains in the joints and epigastrium, tingling in the fingers and toes, and vague anxiety. There was some inability to concentrate, and perception time was slower. In about half of the students, there was a period of elation, followed by dullness and drowsiness. In the rest, there was no elation, but there was irritability and impaired performance on the psychological tests. In the 9 patients, the somatic complaints were essentially the same as those in the students, but they were less pronounced and less frequent. Several of the patients showed excitement, loss of inhibition, overt sexual advances, and exaggerated self-esteem; others were dull and drowsy. The students made 45.4 per cent more errors in an attention and recall test after 13 per cent oxygen; the patients showed 19.2 per cent fewer errors as compared with their performance in normal air. The Rorschach test after low oxygen showed only superficial mood changes. Of the 17 students, 11 were elated, and 6 showed a tendency toward depression with a reduced ability to form new and original associations.

It appears that hypoxia exposes and exaggerates the preexisting tendencies to react according to fundamental inherent patterns. Inhalation of high oxygen atmospheres by patients with previously existing chronic hypoxia has also been found to produce a profound disturbance in mental functioning. Irritability, stupor, and delirium may supervene within 3 hours of exposure to 50 per cent oxygen.

However, when these patients become acclimatized to raised oxygen tension, the mental disturbance disappears and is frequently replaced by a cheerful and optimistic mental state.

Breathing progressively lower oxygen mixtures, human beings show evidence of performance deficits and central nervous system disturbances that are mild at first and are, for the most part, compensated. With mixtures simulating altitudes of 5,000 to 7,000 feet, there may be visual disturbances, for example, in the appreciation of color. At simulated conditions of approximately 10,000 feet, there is increasing deficit in performance, speech intelligibility, and concentration of attention. Subjects become bored, somnolent, and unreliable in their tasks. As is well known, however, acclimatization to much higher altitudes is possible, and the limits of acclimatization appear to be at oxygen levels simulating altitudes of around 18,000 feet. Some subjects will not break down until around 20,000 feet or higher. Victims of hypoxia become euphoric and unconcerned for their safety and may exhibit behavioral abnormalities resembling acute alcohol intoxication.

The pathological manifestations in the central nervous system following death from hypoxia are severe and definite. In the case of a man deprived of oxygen for a period of 5 to 10 minutes, there were severe degenerative changes in the cerebral cortex (particularly in the motor and visual areas), in the putamen, and in the cerebellum.

The neuropsychological effects of low oxygen tensions due to high altitudes are essentially similar to those caused by low oxygen mixtures at ambient pressures. There is progressive deterioration in performance of tasks requiring attention and striking loss of concern for the dangers of the situation. Hypoxic problems at high altitudes are correctly prevented by breathing mixtures of gases with progressively increasing percentages of oxygen up to 100 per cent (which permits support in altitudes of 40,000 to 45,000 feet) or, preferably, by pressurization of the cabin or capsule (now standard procedure).

Oxygen intoxication. Breathing oxygen at pressures greater than 2 atmospheres causes characteristic signs and symptoms of muscle twitching, irritability, vertigo, nausea, vomiting, changes in mood and behavior, and generalized convulsions with loss of consciousness.

Under some circumstances, rapid decompression to sea level from simulated high altitudes or administration of oxygen following a period of hypoxia results in untoward psychological, cardiovascular, and neuromotor signs and symptoms. There may be mental confusion, cardiovascular decompensation, muscular incoordination, and convulsions. These effects are spoken of as the *oxygen paradox*. Psychic changes were observed by Comroe et al. in 8 out of 65 patients. The mechanism for this response to oxygen may possibly involve carbon dioxide narcosis,

cerebral vasospasm, reflex depression, increased cerebrospinal fluid pressure, or direct depression of the cerebral cortex by high oxygen tensions. In one test by Latham, 60 exposures of 52 people to 20,000-foot simulated altitude were made. Thirteen of these showed paradoxical symptoms during oxygen administration. Writing test errors reached a peak 12 seconds after oxygen inhalation at simulated altitude. Cardiovascular responses followed approximately 40 seconds later, and these were accompanied by muscular incoordination and mental confusion. Later, there was threat of cardiovascular collapse, associated with a fall in blood pressure and an increase in peripheral flow.

Carbon dioxide. In the earlier literature, attention has been called to muscular spasms, cramps, and hallucinations in human subjects exposed to 6 or 7 per cent carbon dioxide. Breathing 6 or 7 per cent carbon dioxide causes a prolongation of the time required for addition and cancellation tests and also increases the number of mistakes. Concentrations of 3 or 4 per cent carbon dioxide can be borne for short periods with no mental disturbances, and, in some subjects, concentrations as high as 6 per cent can be tolerated briefly. A 5 per cent carbon dioxide mixture is extremely disagreeable, and probably no human subject will remain conscious for more than 15 minutes breathing a 10 per cent carbon dioxide mixture. Possibly 4 to 6 per cent carbon dioxide may be tolerable for a brief period, but at a concentration of 8 to 10 per cent the limits are nearly reached. At 10 to 12 per cent carbon dioxide, there is unconsciousness if exposure is prolonged for more than 10 minutes. Levels up to 15 per cent are tolerable for only 1 to 2 minutes, and concentrations of 15 to 25 per cent are irrespirable except for a few seconds. At such concentrations, human subjects suffer from laryngeal spasm, headache, dyspnea, gross mental confusion, and psychosis. At concentrations of 25 per cent and above, there is complete narcosis and convulsions either during or after exposure.

Up to 10 per cent, carbon dioxide appears to act as a respiratory and cardiovascular stimulant, but above this critical level the respiratory depressant effects of the gas begin to appear. Exposure to 5 or 6 per cent has been found to cause mental depression, ataxia, dizziness, and fatigue. In studies of 6-day exposures of human subjects to an atmosphere containing 3 per cent carbon dioxide, it has been found that, during the first 24 hours, there is an excitatory effect succeeded by depressive reactions.

Therapeutic administration of carbon dioxide to psychiatric patients has resulted in widespread alterations of activity of the central nervous system, ranging from sensory phenomena to complicated dreams, temporary states of confusion, and hallucinations.

Carbon monoxide. Since carbon monoxide acts to reduce the oxygen-carrying capacity of the blood,

the signs and symptoms of carbon monoxide intoxication are those characteristic of oxygen lack at the level of the tissues and particularly of the central nervous system. After acute carbon monoxide poisoning, there may be permanent brain damage; histopathological changes are found in the globus pallidus and the substantia nigra. Repeated and prolonged exposures to toxic concentrations of carbon monoxide in poorly ventilated closed spaces may also result in illness. Because of this potential danger of chronic exposure, the maximal allowable concentration of this gas has been set by the United States Department of Labor at 0.01 volume per cent (100 parts per million).

Nervous and mental sequelae in carbon monoxide poisoning tend to be relatively infrequent. In one study, out of 21,143 cases of carbon monoxide poisoning in New York City, only 43 had any after-effects, and, of these, only 9 showed chronic signs and symptoms referable to the nervous system. Although comparatively rare, the mental and neurological after-effects of carbon monoxide asphyxia are often very trying from the point of view of treatment and are characterized by severe disability or deterioration of the personality.

A woman victim of accidental carbon monoxide poisoning who survived for 15 years after the original accident exhibited gross disturbances of neurological and mental function. She developed partial amnesia, diminished self-control, and violent flare-ups of temper, and she became secretive and subject to irrational behavior. As time went on, she became sleepless and restless and developed tremors. There were parasthesias, which she described as a "creepy feeling all over." There was also numbness of the legs. It became more and more difficult for her to concentrate; she was confused and tended to repeat words and phrases. She exhibited rhythmic picking at her clothes, tremors of the left arm and leg, exaggerated reflexes, bilateral ankle clonus, and a thick, mumbling speech. There was also poverty of ideas, and she had a rigid, inexpressive face with staring eyes. At autopsy, large bilateral symmetric necrotic lesions of the globus pallidus were seen, and there were areas of softening and small glial scars throughout the cortex, with corresponding areas of demyelination, mild vascular changes, and neuronal destruction in the caudate nucleus and Ammon's horn.

A remarkable case with a favorable outcome was that of a patient of 59 who was asphyxiated by exhaust gas and who went steadily downhill for 2 years to a state of well-advanced parkinsonism. The patient became subject to generalized convulsions, and there was personality deterioration. Three years after the accident, improvement began; 3 years and 8 months after the accident, he was almost completely recovered and able to return to work.

Another case is that of a man who was revived after a suicidal attempt in which there was subsequent loss of ability to perform certain skilled acts. Agraphia was also present. Convulsive disorders subsequently developed. The patient was unable to learn through concrete examples, and a carefully planned retraining program was devised in which all instructions were completely verbalized. By this means, the function of writing was returned to the patient.

In another case, a 35-year-old lawyer was found unconscious in a car in his garage. His subsequent course was characterized by a psychosis in which there were symptoms of depression and amnesia. There was also peripheral neuritis. When last seen, 13 months after the carbon monoxide poisoning, there was general

improvement. It is to be noted that the poisoning may have been a suicidal attempt and that the patient was depressed and agitated before the presumed accident.

In another case of severe carbon monoxide poisoning, coma lasted for 12 days. At the end of 16 days, the patient could speak but was uncooperative and surly. He did not recognize his friends, and there was loss of memory. There were also signs of parkinsonism. These symptoms disappeared in about a month. He complained of severe pains in the legs and feet, and there was toe drop on the right side. The peripheral neuritis as well as other symptoms abated slowly, and in 1 year he was able to resume his professional activities. In 2 years, he was completely well.

In the case of a 34-year-old man who attempted suicide by carbon monoxide, there was unconsciousness for 72 hours. Previously, the patient had been an excellent student, a skilled pianist, and a business executive. Eighteen months after poisoning, he exhibited schizoid disturbances. Space perception was impaired, and typing, playing the piano, and matching colors were impossible. There were no hallucinations or delusions.

Carbon monoxide poisoning in 15 patients who were previously mentally ill has been discussed by Van Amberg. Four of these patients, who had had sufficient gas for acute symptoms but were not unconscious, developed no neurological or mental changes. Four patients who were unconscious up to 30 minutes developed no new clinical signs or symptoms. In two patients who were unconscious for about 1 hour, there were transient neurological defects. Five patients who were unconscious from 3 hours to 5 days showed great variability of recovery. Van Amberg has pointed out that a patient poisoned with carbon monoxide is not likely to have serious sequelae if he regains consciousness within 1 hour after removal from the toxic atmosphere. Beyond this point, there appears to be no correlation between the duration of unconsciousness and the severity and permanence of the clinical changes. There seem to be no important clinical differences between the toxicity of motor exhaust gas and that of illuminating gas. Other clinical observations indicate that the danger of psychotic reactions are greater if the coma persists longer than 36 hours.

Diagnosis. The diagnosis of carbon monoxide poisoning is aided by the history of exposure and by the cherry red color of the mucous membranes, skin, and finger nails; the final diagnosis is confirmed by the presence of carboxyhemoglobin. Subjective sensations are noted when the carboxyhemoglobin reaches 30 per cent, and a saturation of 50 per cent usually connotes mental involvement, with cerebral and cardiac lesions.

Treatment. The treatment of carbon monoxide poisoning has been reviewed extensively by Hoff and Greenbaum. The victim must be transferred from the toxic atmosphere and given oxygen by means of an appropriate respirator. Pending this, artificial respiration must be maintained manually or orally if there is respiratory paralysis. Although administration of oxygen with 5 or 7 per cent carbon dioxide has been recommended in the past, there appears to be no practical value of oxygen-carbon dioxide mixtures as

opposed to pure oxygen. Blood transfusion may be a helpful procedure. In cases where cardiac arrest has supervened, intracardiac administration of epinephrine and atropine has been considered worthy of trial as a last resort. Supportive measures, such as warmth, absolute quiet, and hypothermia, have been recommended. Administration of oxygen under a pressure of 2 atmospheres has been found to accelerate the elimination of carbon monoxide and to promote recovery. The intravenous injection of 100 cc. of 15 per cent saline solution has been used to relieve headache and mental confusion.

Gasoline. Inhaling gasoline may become a tempting, recurrent activity in children and adolescents, and habituation has been reported. Repeated use causes extensive salivation, drowsiness, weakness, light-headedness, nausea, amnesia, and a sense of physical lightness, spinning, and floating, with distorted space perception. There may also be hyperacusis and visual, auditory, and tactile hallucinations. It is to be noted that transient euphoric states somewhat similar to acute alcohol intoxication can be produced by inhalation of kerosene vapor.

Solvents. Intoxication with carbon tetrachloride is usually the result of inhalation of the vapor in industrial environments, but it may follow its ingestion accidentally or with suicidal intent. This substance resembles chloroform in its action on the central nervous system. Intoxication may be associated with motor disturbances, nausea, vomiting, anorexia, depression, apathy, and mental confusion. With continued exposure under chronic conditions, there are evidences of kidney and liver damage. Neurological and psychiatric symptoms may also be produced by methylbromide and methylchloride.

The fat solvent carbon disulfide can produce toxic effects on the nervous system and various psychotic states or, short of this, irritability, loss of memory, disturbed sleep, and terrifying dreams.

Attention should likewise be directed to the problem of deliberate inhalation of vapors of highly volatile solvents used in lacquers, enamels, paint removers, etc. This "glue sniffing" by children and adolescents may produce toxic effects, such as unsteadiness of gait, slurring of speech, double vision, and ringing in the ears, as well as excitement, euphoria, and exhilaration. Victims of the practice may become drowsy and stuporous or lose consciousness. Since glue sniffing may become habitual and since a person under the influence of these vapors may commit dangerous and irresponsible acts, the problem deserves serious therapeutic and preventive attention.

Metals

Mercury. Chronic mercurialism may result from exposure to small amounts of mercury over extended periods of time in industrial situations when mercury or its salts are used. Chronic mercury poisoning may be characterized by disturbances of the alimentary

tract, renal damage, anemia, high blood pressure, and peripheral neuritis. The central nervous system may be involved, with tremors varying in degree from a slight tremor of the hand, eyelid, or tongue to marked generalized tremors and shaking. There may be irascibility, depression, despondency, excessive embarrassment in the presence of strangers, timidity, desire for solitude, and sometimes hallucinations.

Lead. Chronic inorganic lead poisoning is an industrial hazard that in its more intense manifestations has been greatly reduced by preventive and protective measures. For example, in the United States Navy between 1922 and 1944 there was a reduction in the incidence of lead poisoning due to the change in 1931 from a paint containing 70 per cent red lead to one containing only 29.5 per cent and to the change over to zinc chromate paint in 1941. Probably improvements in hygienic control were of even greater importance. Shipbreaking during the 2 years immediately after World War II produced very few cases of plumbism, a condition common in this occupation after World War I.

The route by which lead enters the organism most rapidly is the respiratory tract, and lead absorbed by this route produces the most serious symptoms. Next in danger comes the continued ingestion of lead compounds by mouth. The least harmful of all the possible routes is a slow cutaneous absorption in persons with broken or irritated skin.

Lead compounds may reach the mouth by contaminated hands; or lead fumes may be inhaled during grinding or filing, during painting with lead paints, or during cutting, burning, or chipping of lead-painted surfaces. A number of other occupational sources of intoxication exist. The upper limit of safety for industrial lead exposure by inhalation has been given as 1.5 mg. per 10 cubic meters of air. The upper limit of safe urinary excretion of lead does not exceed 0.15 mg. per liter of urine. The safe level for ingestion of lead in food and drink is greater than 0.3 and less than 0.6 mg. per day. It is significant physiologically that 95 to 98 per cent of lead present in the body in lead poisoning is found in the red blood cells. Only a small quantity of the lead ingested is absorbed into the body. The absorbed portion is distributed to the tissues, including the liver, from which it is partially secreted back into the alimentary tract with the bile. This action of the liver in withdrawing lead from the body and secreting it into the alimentary tract is responsible for the fact that ingestion of lead is less dangerous than its inhalation.

The toxicity of lead depends on a number of factors: its solubility in body fluids; the length of time in contact with the body fluids; the quantity ingested, inhaled, or absorbed; and the quantity in circulation at any given time. The most consistently harmful effect of abnormal lead absorption is on the blood cells, and anemia is invariably present. Gastrointestinal symptoms and signs are numerous and tend

to result from very slowly developing intoxication over long periods of time. There is loss of appetite, constipation, and lead colic. The mechanism of this intestinal colic in lead poisoning is not clearly understood. Usually, other symptoms precede the colic. The gastrointestinal symptoms generally begin with loss of appetite, a disagreeable, sweetish taste in the mouth, dyspepsia, and obstinate constipation. There is also lassitude and malaise, with pain around the umbilicus and spasmodic contraction of the abdominal wall. The colic is typically decreased by pressure, and there is no tenderness. This colic has been ascribed by some authors to vagal irritation produced by the lead. There is basophilic stippling of the red blood cells and the "lead line" along the lower incisors at the gum margin.

More intense exposures to inorganic lead compounds result in neuromuscular and central nervous system effects. A characteristic phenomenon is wrist drop due to paralysis of the extensor muscles of the forearm. There may be considerable wasting of the muscles. Lead palsy is seen in diminishing frequency at the present time. A most serious condition occurring as a result of rapid absorption of lead is lead encephalopathy. This may begin with motor incoordination, ataxia, headache, sleeplessness, and irritability. As the condition develops, there may be increased intracranial pressure, convulsions, excitement, confusion, delirium, lethargy, and coma. There also may be disturbances of vision and projectile vomiting. In patients who die—and the condition is frequently fatal—there may be edema of the brain and signs of proliferative meningitis. Approximately 25 per cent of the patients succumb, and, in about 20 per cent of those who survive, there is a residual paralysis. The survivors may also be permanently impaired mentally.

Although the dangers from contact with leaded gasoline are now greatly reduced, tetraethyl lead and tetramethyl lead are potentially toxic. Chronic poisoning from inhaling tetraethyl lead may produce early symptoms of sleeplessness with terrifying dreams, followed by loss of appetite, nausea, vomiting, diarrhea, headache, weakness, and emotional lability. The victims are irritable, restless, and anxious. More serious manifestations include delirium and delusional states. Finally, there may be maniacal excitement with convulsions or coma.

Prevention. Prevention of lead poisoning can be accomplished by various measures to minimize and control exposure by inhalation, ingestion, and contact with the skin either to inorganic or organic lead compounds. Prevention of pediatric poisoning by protecting children from persistent ingestion of lead-containing substances is highly important.

Treatment. Formerly, treatment consisted of a high calcium diet and large amounts of vitamin D. Presently, dimercaprol (BAL) is used initially to increase urinary lead excretion, followed by calcium

disodium edetate. Colic may be relieved by antispasmodics, such as atropine, or by intravenous administration of calcium gluconate (2 gm.). Morphine may be necessary to relieve the pain. With calcium gluconate there may be an attendant danger of renal calculi. The oral use of penicillamine may be of value in treating lead poisoning. The alleviation of convulsions and psychotic symptoms may be accomplished by adequate doses of barbiturates.

The use of sodium citrate has been recommended as a prophylactic or therapeutic procedure. Sodium citrate, given in oral doses of 4 or 5 gm. in water once a day as a preventive measure to employees exposed to lead, has been advised. Evidence from a study of stippled cell counts and lymphocytes before and after commencing this prophylaxis suggests that sodium citrate is indeed useful in preventing ill effects of increased lead absorption. However, sodium citrate prophylaxis is not a substitute for improved working conditions. Sodium citrate has also been used intravenously in the relief of lead colic.

Manganese. Manganese poisoning is a hazard in the mining and the processing of manganese ores and in the use of manganese alloys in the steel and chemical industries. The principal source of manganese toxicity is exposure to manganese-containing dusts. The major route of entry into the body is the respiratory tract and is virtually the only route to be considered. The cutaneous route appears to be insignificant, and the amount of manganese absorbed by ingestion is minimal and presumably without danger. The fact that there is continuous elimination of manganese long after exposure suggests that there are deposits in the body, probably in the lungs, kidneys, liver, intestines, heart, bone, brain, and stomach. There is general agreement that most of the excretion is by the feces through the bile. Length of exposure before toxic manifestations appear depends upon the concentration of the substance in the air, individual sensitivity, and number of hours of exposure daily. The shortest exposure reported has been 49 days and the longest 480 days, with an average of 178 days.

The manifestations of onset are usually subjective, which often makes early diagnosis difficult. It is important, however, that the intoxication be recognized as early as possible to separate the individual from the exposure. The most frequent early symptoms are headache, weakness, increased sleepiness, spasms in the legs, joint pains, and irritability. Psychological disturbances usually appear before neurological manifestations and may be unaccompanied by the latter. There may be psychomotor irritability associated with impulsive acts, such as a deep desire to walk and to work. There may be euphoria, absent-mindedness, mental confusion, aggressiveness, and hallucinations. This toxic psychosis due to manganese may involve the victim in the commission of crimes and other uncontrolled behavior.

The chronic toxicity is characterized by neurological lesions involving the basal ganglia, the frontal cortex, and occasionally the pyramidal system. The headache is of variable intensity, location, and duration. The muscles are sensitive, and there may be back pains. The gait is impaired, and there are equilibratory disturbances. When walking, the patient experiences difficulty in stopping, especially when he is walking on an incline. When the patient walks backward, he finds it difficult to keep from falling down. There is a monotonous speech, often with inability to vocalize louder than a whisper. Speech may be unintelligible, and pauses between words disappear. There are frequently tremors, particularly in the tongue, arms, and legs. The tremors are present at rest and become increased during movement. They are most frequent during the night but may appear at any time. There is a characteristic immobility of facial expression, the "manganese mask." The patient may also have persistent, unmotivated laughter that is uncontrollable. Handwriting is irregular, and there is micrographia, with a tendency to run words together on the page. Brain changes include atrophy, and the most significant pathological processes are found in the basal ganglia, in which there is degeneration of nerve cells, satellitosis, and gliosis. The medulla, peripheral nerves, and muscles may also be involved in long-standing cases. The condition is usually not fatal.

The psychological disorders may not be diagnosed, since the patient may not report them until the transitory psychosis has cleared and the neurological disorders have become manifest. Upon removal from exposure, the psychological effects tend to clear relatively quickly. In some cases, the psychological disorders disappear within 3 or 4 months with no other disturbances or are followed by the neurological symptoms, which tend to be progressive with partial or total disability. Some cases reach a complete paralysis, and others are stationary for years. Partial neurological recovery appears in a few cases, but the lesions of the nervous system are considered to be irreversible.

There is no specific treatment for manganese poisoning, and the management of the psychotic manifestations are symptomatic and supportive. Dimercaprol has not proved effective in arresting the progressive manifestations. One case is reported of good recovery of the neurological condition by the use of calcium diethylenediaminetetraacetic acid. The mental symptoms also cleared.

20.3 BRAIN SYNDROMES ASSOCIATED WITH INFECTION

DONALD W. MULDER, M.D.

ALLAN J. D. DALE, M.D.

Introduction

Infectious diseases give rise to brain dysfunction, either by direct invasion of the brain or by effects that are often toxic, hypoxic, or allergic from infec-

tion elsewhere in the body. Mental and behavioral changes commonly occur in these cases, although these changes are nonspecific and have no relation to the specific organism involved.

Mild effects, such as irritability, insomnia, and restlessness, may appear early in the illness but subside completely if the infection is overcome rapidly. With progression of the infection, more severe changes develop, such as combativeness, visual hallucinations, impairment of memory and alterations in consciousness such as lethargy, drowsiness, stupor, and coma. Ordinarily, these manifestations clear up as the infection is brought under control, but changes of personality and intellect persist in a significant number of patients as sequelae of the infection. For example, viral encephalitis is often followed by subjective symptoms, such as nervousness, irritability, lassitude, and defects of memory. Meningitis and encephalitis are less commonly followed by more severe sequelae, such as mental retardation, dementia, and marked instability of emotions and personality.

Any infection may at some time present itself as intracranial, for the central nervous system offers less resistance to infection than any other tissue of the body. Intracranial infections are usually localized in the subarachnoid space (meningitis), spread diffusely within the brain (encephalitis), or confined to encapsulated regions within the brain or meninges (abscess). Actually, the involvement is seldom restricted in this fashion. Meningitis always affects the brain to some extent; encephalitis, early in its clinical course, usually is accompanied by meningitis. Brain abscess begins as a more diffuse encephalitis that only later in its clinical course becomes localized or encapsulated.

Bacterial Infections

Tuberculous meningitis. The incidence of meningeal infection with *Mycobacterium tuberculosis* has been decreased by antituberculous drugs, but it remains an important cause of death in patients who have tuberculosis, especially miliary tuberculosis. All patients with tuberculous meningitis have tuberculous infection elsewhere in the body, often in the form of miliary tuberculosis or an active primary focus, but some have no clinical evidence of active tuberculosis except the meningitis. It is most often seen in patients between the ages of 6 months and 20 years.

Pathology. Tuberculous meningitis probably develops as a result of spread into the subarachnoid and ventricular spaces from foci in the meninges or choroid plexus. These, in turn, have developed from spread of the infection from an active primary focus elsewhere or in association with miliary tuberculosis. Prior to the use of antituberculous drugs, surgical removal of a tuberculoma from the brain was very often followed by diffuse tuberculous meningitis.

Characteristically, the meninges are thickened and opaque, and small tubercles may be seen in sulci or

on the dura. A heavy, gelatinous exudate is present, especially in the basal cisterns and sylvian fissures and over the dorsal surface of the spinal cord. The exudate consists of lymphocytes, plasma cells, macrophages, occasional giant cells, and *M. tuberculosis*. If the disease continues long, the exudate may become very thick and obstruct the flow of cerebrospinal fluid. Meningeal vessels are inflamed and may become thrombosed, leading to infarction of the brain, especially in the hypothalamus or basal ganglia. The inflammatory process may extend into the superficial cortical layers of the brain, but widespread involvement of the brain substance does not usually occur.

Symptoms and signs. The disease develops over a period of several days to several weeks and is accompanied by fever, headache, vomiting, nuchal stiffness, and lethargy. Among young infants it may be evidenced by increasing irritability, a shrill cry, and bulging of the fontanelles. Stupor may develop and then coma. Papilledema, optic atrophy, convulsive seizures, cranial nerve palsies, and other focal neurological signs may appear as the disease progresses.

The changes in the cerebrospinal fluid are not specific for the disease, but together with the clinical pattern they should lead to the diagnosis in most instances. The fluid is under increased pressure; it is clear and tends to form a coagulum on standing. The cell count is moderately increased, and lymphocytes predominate, although a few leukocytes may also be present. The concentration of protein is moderately elevated, especially when the disease has been present for several weeks or more. The sugar and chlorides are significantly decreased. The Wassermann reaction is negative.

Very often the organism may be seen on smears of the spinal fluid stained by the acid-fast Ziehl-Neelsen method, but absolute identification depends on cultures and guinea pig inoculation. These require some weeks for positive results to appear, and treatment should never be delayed for this reason if the diagnosis is probable on the basis of information available. The tuberculin test, if its result is positive, may be of value in cases of infants or young children; but it is well to remember that this may be positive in many adults who do not have tuberculosis. It may also be negative in the face of overwhelming miliary tuberculosis.

To be considered in differential diagnosis are mycotic meningitis, viral meningoencephalitis, bacterial meningitis, syphilitic meningitis, and meningeal carcinomatosis. Usually the clinical pattern and the findings from the cerebrospinal fluid help one make an accurate diagnosis.

Prognosis. Without proper treatment by antituberculous drugs, this disease is fatal, usually within 3 to 4 weeks of its onset. Use of these drugs has reduced the mortality significantly and has produced cures. Rarely will relapses occur in adequately treated patients.

Approximately 25 per cent of the survivors have some neurological sequelae. Cranial nerve abnormalities such as deafness, blindness, and facial paresis may be noted, and seizures and hemiparesis are common. Intellectual impairment may occur. Occasionally, calcification within the base of the skull is identifiable on roentgenograms made several years later.

Treatment. When tuberculous meningitis is suspected and the clinical and spinal fluid evidence supports the suspicion, proper chemotherapy should be instituted promptly. Spinal fluid should have been obtained previously for positive diagnosis by culture and guinea pig inoculation, but therapy should not be delayed for these reports. The prognosis and development of neurological sequelae are related to quickness and adequacy of treatment. A combination of streptomycin, isoniazid, and *p*-aminosalicylic acid is preferable to any of the three alone, and administration of the latter two drugs should be continued for 12 to 18 months. Streptomycin is preferred over dihydrostreptomycin, and 2 to 3 weeks of intramuscular therapy is usual, since longer periods of administration bring a high risk of ototoxicity. Intrathecal administration of streptomycin is not currently advocated.

Meningitis from various bacteria. Inflammation due to bacterial infection of the leptomeninges covering the brain and spinal cord remains an important cause of illness and death, despite the advent of antibiotic therapy. The reported mortality varies from 17 to 30 per cent, and the incidence of major neurological sequelae is approximately 20 per cent.

Etiology. Infections with *Neisseria meningitidis*, *Diplococcus pneumoniae*, and *Haemophilus influenzae* are responsible for the majority of cases. Forty per cent of the 294 cases seen at the Mayo Clinic reported by Eigler et al. and 70 of the 207 cases seen at the Massachusetts General Hospital reported by Swartz and Dodge were due to these organisms. Meningococcal meningitis, the commonest of all, may occur sporadically in epidemics, especially where large groups of relatively nonimmune individuals are found, as in military barracks. Infants and children are frequently stricken; all cases of meningococcal meningitis in one series occurred among patients less than 20 years old. Pneumococcal meningitis occurs more readily in infants or in the elderly, and *H. influenzae* is the commonest cause of bacterial meningitis in infants and young children.

Infection by streptococci and staphylococci (principally *Staphylococcus aureus*), though less frequently encountered, produces the next most important group of cases. A wide variety of bacteria such as *Escherichia coli* (especially in the newborn), *Pseudomonas aeruginosa*, and *Listeria monocytogenes* are responsible for occasional cases. Occasionally, meningitis is the result of infection by more than one kind of bacteria.

Pathogenesis. The leptomeninges offer little resistance to infection, and pathogenic microorganisms

reaching them—whether by direct extension from a focus of infection, by the agency of head trauma or surgery, or by hematogenous spread from a distant source of infection, such as the lungs or urinary tract—spread easily throughout the subarachnoid space. Certain factors, such as advanced age, carcinomatosis, cerebrospinal fluid rhinorrhea, and the extensive antibiotic or steroid therapy, enhance the possibility of intracranial infection. Extension from a focus of purulent sinusitis or purulent otitis media, a frequent source of infection in previous years, has had less importance since the use of antibiotics has become common. Nevertheless, in 25 to 30 per cent of patients with meningitis due to pneumococci or *H. influenzae* or with purulent meningitis due to unknown organisms, otitis media may be associated. Lumbar puncture may be followed by bacterial meningitis, most often due to *P. aeruginosa* or *S. aureus*.

Meningococcal meningitis is a sequel to meningococcal bacteremia (meningococcemia), either acute or chronic, and is caused by seeding of bacteria into the ventricular cerebrospinal fluid from choroid plexuses infected with blood-borne organisms. The initial site of infection is the nasopharynx, where it may or may not be detectable clinically. On occasion, meningococcemia may be acute and overwhelming, producing acute adrenocortical failure with shock and widespread purpuric lesions and purulent meningitis. Such developments bring significant mortality in spite of all therapeutic efforts. In some patients, meningococcemia is a chronic indolent process lasting weeks or months and sometimes causing meningitis.

Pathology. In the acute phase of purulent meningitis, the meninges first become hyperemic and infiltrated with inflammatory cells, such as polymorphonuclear leukocytes, lymphocytes, and plasma cells. Exudation of these cells into the subarachnoid space follows, and soon a thick purulent exudate is present. In a few instances, particularly with meningitis due to *Bacillus anthracis*, the exudate is frankly hemorrhagic. At first it fills the basal cisterns and infiltrates around the cranial nerves; then it spreads over the cerebral hemispheres into the fissures and sulci. In addition, by a gravitational effect, the spinal subarachnoid space becomes involved, especially over the dorsal aspect of the cord. Sectioning of the brain may reveal scattered petechiae and the beginnings of small abscesses, evidenced as focal softenings. In the cerebral cortex small necrotic infarcts can be found; they may or may not be associated with thrombosis of nearby vessels or sinuses.

Microscopically, the exudate in the subarachnoid space consists of many inflammatory cells, necrotic material, and bacteria. If the infection persists, fibroblasts from the meninges and vessel walls gradually infiltrate the exudate, and collagen fibers appear, producing meningeal thickenings and adhesions. Loculation may result, and impaired flow of cerebrospinal fluid may produce hydrocephalus, or an intraspinal

mass of fibrous tissue may cause paraplegia. On the other hand, in a patient successfully treated, no abnormality of the central nervous system may be found on postmortem examination years later.

Clinical pattern. Bacterial meningitis is an acute illness in most instances. Nonspecific symptoms such as malaise, headache (often an initial symptom), fever, nausea, and vomiting, are common. Often photophobia is present. Lethargy or agitation and confusion with disorientation and hallucinations occur in numerous cases. Stupor or coma may supervene, especially if the illness has been present many hours or days. Seizures frequently occur, particularly in infants, and may suggest intracranial venous thrombosis or development of an intracerebral abscess.

On examination, nuchal rigidity is to be found in almost every case, and Kernig's and Brudzinski's signs of meningeal irritation are often associated with it. Focal cerebral signs, such as hemiparesis, visual field defect, and aphasia, may be demonstrated in some patients; cranial nerve abnormalities, especially of the oculomotor, abducens, and eighth nerves, are frequently encountered. Many of these subside with recovery from the illness. Babinski's sign may be present. Papilledema, a rare finding, may indicate a developing brain abscess, or it may presage venous sinus thrombosis.

A petechial skin rash is frequently seen during meningococcal meningitis. If it is severe, the lesions, which are sterile, may become purpuric. But fever, headache, and petechial rash may be encountered in other illnesses, too, such as Rocky Mountain spotted fever and ECHO 9 viral meningitis.

Examination of cerebrospinal fluid reveals definite elevation of fluid pressure in many patients. The fluid is characteristically turbid and may form a coagulum on standing. The leukocyte count is high—sometimes more than 10,000 per cubic millimeter—and polymorphonuclear cells usually predominate. Often the protein amounts to several hundred milligrams per cubic millimeter, and the concentration of sugar is significantly depressed. Hypoglycorrhachia is probably a reflection of the presence of large numbers of actively phagocytosing leukocytes. The value for chlorides may be low. Smear and culture of the fluid make identification of the responsible organism possible in most instances.

The importance of bacteremia in bacterial meningitis should be emphasized, for blood cultures may allow isolation of the causative organism. In one series, bacteremia was demonstrated in 52 per cent of all cases in which blood cultures were attempted.

Possibilities for differential diagnosis include viral meningoencephalitis, tuberculous meningitis, fungal meningitis, postvaccinal and postinfectious encephalomyelitis, subarachnoid hemorrhage, and, on rare occasions, meningeal carcinomatosis, Behçet's disease, and the aseptic meningeal reaction associated with myelography or an intracranial epidermoid tumor.

Differentiation can usually be made on the basis of clinical and spinal fluid findings.

In a significant number of cases of purulent meningitis (7 to 9 per cent in two series), the result of bacterial culture is negative. Most often, the patients have been treated with antibiotics. Sometimes organisms are recognized in smears of their spinal fluid.

Prognosis. Certain factors appear to predispose patients to increased mortality, such as coma, bacteremia, extremes of age (neonatal or advanced), underlying disease, and coexistent trauma. Heightened intracranial pressure is an important cause of death in acute bacterial meningitis. However, those cases with early diagnosis and adequate treatment do have a favorable prognosis. Sequelae occur, especially in infants, as convulsive disorders, deafness, mental retardation, hemiparesis, and hydrocephalus.

Treatment. Successful treatment rests on early diagnosis, isolation of the causative organism, and prompt, adequate antibiotic therapy adapted to the sensitivities of the organism (see Table I). Prior to identification of the organism, empiric therapy with a combination of penicillin, sulfadiazine, and chloramphenicol may be instituted after cerebrospinal fluid and blood have been drawn for cultures.

Meningococcal meningitis may be treated adequately with sulfadiazine alone or with penicillin alone. Often these two drugs are used in combination, although the need for this is uncertain. The organism remains sensitive to these two drugs. Pneumococcal meningitis is best treated with penicillin given parenterally in large dosage (12 to 20 million units daily), for the organism is characteristically sensitive to this drug. Chloramphenicol, alone or in combination with sulfadiazine, may be used effectively for meningitis due to *H. influenzae*, as can a combination of strepto-

mycin and tetracycline. Penicillin is effective against streptococcal meningitis; and the newer penicillin derivatives, such as methicillin, oxacillin, and nafcillin, may be employed for meningitis due to penicillin-resistant staphylococci.

Intrathecal therapy is usually not indicated, but in severe infections, polymixin B sulfate may be used against organisms such as *P. aeruginosa* and bacitracin against *S. aureus*.

Mycotic Meningitis

Infection of the meninges and central nervous system results from invasion of various pathogenic fungi, most frequently *Cryptococcus neoformans*, *Coccidioides immitis*, and *Histoplasma capsulatum*. Implicated less often are other fungi, such as *Candida albicans*, *Nocardia asteroides*, and *Blastomyces*, and, rarely, mucormycosis due to *Rhizopus* and aspergillar organisms. The fungi may gain entrance to the body through the respiratory tract. They may spread secondarily to the central nervous system or become pathogens in a patient who has an underlying malignant disease or who has had extensive treatment with antibacterial agents or steroids. Cryptococcal meningitis occurs in association with lymphoma and leukemia. The less commonly encountered fungi are often secondary invaders.

Symptoms and signs. The pathological changes are similar to those seen in subacute or chronic meningitis due to bacteria. Clinically, the patient presents signs and symptoms of meningitis developing over several weeks or months. In the cerebrospinal fluid the protein content is usually slightly more than normal, the cell count is high, and both lymphocytes and neutrophilic leukocytes are present. The spinal fluid sugar is characteristically decreased, and the alcohol content is increased. Repeated cultures of spinal fluid and blood and special culture techniques and staining procedures may be necessary to make the diagnosis.

Treatment. Formerly, mycotic meningitis was fatal in every instance, but treatment has been more satisfactory in recent years with the development and availability of amphotericin B. However, proper identification of the responsible organism is necessary, as not all fungi are best treated with this drug. For example, *N. asteroides* responds best to sulfonamides, and *Actinomyces bovis* responds better to penicillin. Cryptococcal, coccidioidal, and *Candida albicans* meningitis have been treated adequately with amphotericin B, and cures may result. Administration of this drug requires careful supervision, for toxic side effects, such as fever, elevation of blood urea, and pain and phlebitis at the site of injection, are common. The drug must be given by slow intravenous drip. Treatment usually has to be carried on for many weeks or months.

Viral Infections

Viral infections of the central nervous system may remain primarily in the leptomeninges (lymphocytic

TABLE I
Chemotherapy of Meningitis

Microorganism	Drugs of Choice
<i>Neisseria meningitidis</i>	Penicillin G, sulfadiazine, or both
<i>Diplococcus pneumoniae</i>	Penicillin G
<i>Haemophilus influenzae</i>	Chloramphenicol and sulfadiazine
<i>Staphylococcus aureus</i>	Methicillin or cephalothin first, then adjust according to sensitivities
<i>Streptococcus pyogenes</i>	Penicillin G
<i>Listeria monocytogenes</i>	Penicillin G
<i>Escherichia coli</i>	Streptomycin and tetracycline, or colistin
<i>Mycobacterium tuberculosis</i>	Isoniazid, streptomycin, and p-aminosalicylic acid
<i>Treponema pallidum</i>	Penicillin G
<i>Actinomyces bovis</i>	Penicillin G
<i>Nocardia asteroides</i>	Sulfadiazine
<i>Cryptococcus neoformans</i>	Amphotericin B
<i>Coccidioides immitis</i>	Amphotericin B
Unknown	Penicillin G, sulfadiazine, and chloramphenicol

choriomeningitis) or the spinal cord (poliomyelitis), but more commonly they involve the brain itself. The clinical syndrome of viral encephalitis is remarkably similar in all the viral illnesses. The identification of the responsible virus is often difficult and extensive study frequently fails.

Arthropod-borne encephalitides. One group of viral diseases is carried to man by arthropods from reservoirs, usually in other mammals. These illnesses are found throughout the world, and, although they have different vectors, the clinical syndromes are similar enough to warrant discussing them together. Diagnosis is usually made serologically by demonstrating a rise in the complement-fixation antibody for the specific virus in the affected individual from a time early in the illness to one several weeks later in the convalescent period. The virus itself is rarely identified.

The cerebral pathology consists of small hemorrhages and endarteritis with exudates of small mononuclear cells. Neuronal degeneration and necrosis are prominent.

Western equine encephalitis. This acute infectious disease is caused by a virus that produces specific antibodies. It is characterized by involvement of the central nervous system with encephalomyelitis and is often followed by residua indicative of damage to the central nervous system. It was recognized in epidemic form among horses for many years before Meyer in 1932 identified the virus and in 1933 suggested that it might cause infection in man. Hammon and others have presented proof that the mosquito *Culex tarsalis* has been a vector in certain instances and that fowl may be an important reservoir of the disease.

Diagnosis is confirmed in a suspected case by serum complement fixation tests or by isolation of the virus. Only in rare instances has Western equine virus been isolated from the blood and spinal fluid. Most frequently, the virus is isolated from the brain or spinal cord of patients who have died early in the course of their disease.

Clinical features. The clinical syndrome presented depends in part on the age of the patient. In infants the illness begins abruptly with high fever and convulsions. The convulsive movements are continuous, beginning in one extremity and spreading to the others. The convulsions are preceded and accompanied by an increased temperature, which persists for 3 to 7 days and ranges between 104 and 106° F. The fever and convulsions stop abruptly, and the patient becomes asymptomatic.

Children, on examination during the acute episode, appear acutely ill, with fever and neurological abnormalities. The deep reflexes are more active in the extremity from which the convulsive movements spread. Nuchal rigidity is a prominent finding, and in a few instances opisthotonos is noted. The abnormalities of the spinal fluid are the same in the infantile

form as in other forms of the illness and will be discussed later.

Among adults the severity of clinical symptoms varies considerably. However, a common pattern can be recognized. The illness begins in most instances with fever, chills, and malaise. These symptoms are followed by a headache which is described as prostrating and persistent. In mild cases headache is the only prominent finding; but more frequently it is accompanied by drowsiness, and sometimes by coma. The patient, if awakened, may still complain of headache but fall asleep while expressing his anguish.

This disturbance in the level of consciousness is a consistent finding in severely ill patients. It varies from a slight increase in drowsiness to coma that persists for weeks. Sometimes disturbance in awareness and perception is accompanied by considerable anxiety and delirium. Less severe symptoms include pain in the back, nausea, and vomiting. Back pain is prominent early in the course of the illness but is seldom mentioned by patients because of the severity of headache. Vomiting constitutes a serious threat to comatose patients, who frequently aspirate vomitus.

In milder cases, physical findings are scant and variable. Nuchal rigidity is found in all patients during the acute stage. In more severe cases, tremor, dysarthria, and paralysis or paresis may ensue. Tremor occurs most characteristically about the mouth and in the upper extremities. At times its presence in the upper extremities is associated with typical cogwheel rigidity. Dysarthria affects most of the severely ill patients and is frequently progressive. Speech becomes unintelligible in some cases through loss of volume and quality of the voice. Paralysis and weakness, when present, are not patchy and flaccid in character, as in poliomyelitis; they usually involve either one side of the body or both, but are seldom complete. Associated with them are increased muscle tone, hyperactive reflexes, and abnormal plantar responses. In some instances there is evidence of involvement of the central control of autonomic function, which may be demonstrated by a persistently low fever. Respiratory arrest may occur, necessitating use of a respirator. Eye symptoms, which are common in epidemic encephalitis, are infrequently noted. Convulsive episodes, when they do occur in the adult group, seem related to anoxia.

Laboratory data. During the first few days of illness, spinal tap reveals a mild increase in pressure; the fluid contains 25 to 600 leukocytes per cubic millimeter, the majority being polymorphonuclear cells, and increased concentrations of sugar and protein. The 2nd week brings pleocytosis, with lymphocytes becoming a majority, and increase of total protein. In a few cases, 5 to 10 per cent of the cells found in the spinal fluid are large mononuclears. During the acute infection, examinations of blood demonstrate mild leukocytosis. Other laboratory studies, except for the neutralization tests, are noncontributory.

Outcome of disease. Death occurs in approximately 5 to 10 per cent of cases, usually in the first 48 to 96 hours, from a fulminating type of infection.

Convalescence is prolonged in the adult group and, after severe illness, requires 3 to 4 months. Among infants, recovery, if it does occur, is completed in a few weeks. The sequelae observed in infants are hemiplegia and focal convulsions. In adults, the sequelae are spasticity, speech difficulty, loss of weight, and organic impairment of psychological functioning; their severity seems directly related to the duration of coma.

Treatment and prevention. Treatment for Western equine encephalitis remains symptomatic, as there is no specific therapy for this virus. Supportive therapy is of great value and in many instances is life-saving, especially among stuporous or comatose patients. In coma, maintenance of the airway is essential; the patient should be turned frequently, and the throat should be aspirated when necessary. During the acute phase of the illness, oxygen therapy may be indicated. Sometimes tracheostomy is required, and occasionally use of a respirator is indicated. In the acute period, an adequate intake of fluid must be maintained, parenterally if necessary. Once the acute symptoms have subsided, particularly after the period of vomiting has passed, a nasogastric tube may be used for giving the needed fluid and nourishment. At present, the physician is unable to help the patient appreciably during the acute phase of his illness. He can do a great deal, however, if the patient is able to survive the first 96 hours; even in the presence of prolonged coma, one may expect the patient to recover, although not without residua.

Preventive measures that have proved effective include the use of vaccine and mosquito control. Commercially prepared vaccines have been used on laboratory workers, but in most epidemics the morbidity has been moderate, and, consequently, mass immunization is not indicated. Communities in an endemic area should attempt mosquito control, and the individual should adopt all available methods to prevent mosquito bites.

Other arthropod-borne encephalitides. Eastern equine encephalitis is found on the Eastern seaboard of the United States and causes greater morbidity than does the Western type. Saint Louis encephalitis has been reported in epidemics in the Central United States. Japanese B encephalitis is a Pacific form of arthropod-borne encephalitis in which the human infection is often inapparent. Murray Valley encephalitis is an Australian disease.

Russian tick-borne encephalitis is a biphasic illness with severe residua. Of particular interest is its reported chronic form, which may give rise to a chronic progressive disease of the central nervous system with psychiatric symptoms.

Herpes simplex encephalitis. This is a rare encephalitis caused by the virus herpes simplex. The

most frequently noted effect is disorientation with change of the sensorium. Recurrent psychosis has been reported as a complication.

Mumps meningoencephalitis. Meningoencephalitis develops in 0.5 to 10 per cent of patients with mumps. The neurological complications usually occur from the 3rd to the 14th day after the onset of parotid swelling, although they may begin prior to the parotitis. The clinical pattern is one of changes in the sensorium, with focal neurological findings, such as hemiplegia. The cerebrospinal fluid shows some pleocytosis. Recovery is usually complete.

Other viral infections of the nervous system that characteristically involve the central nervous system include rabies, herpes zoster, poliomyelitis, lymphocytic choriomeningitis, and the various Coxsackie viral diseases. And still other viruses occasionally involve the central nervous system and produce mental symptoms.

Spirochetal Infection: Syphilis

Syphilis is a chronic, systemic, infectious disease caused by the *Treponema pallidum*, which is usually transmitted by sexual contact. In the majority of cases it invades the central nervous system; hence it is included among the primary cerebral infections, although only a small number of patients (10 to 15 per cent) develop late manifestations of central nervous system syphilis.

This disease at one time accounted for 10 to 20 per cent of admissions to state hospitals for the insane and has always been considered in the differential diagnosis of any case with mental symptoms. With the advent of effective therapy, syphilis of the nervous system is becoming a medical curiosity.

The causative organism, *Treponema pallidum*, is a slender, corkscrew-like spirochete with regular, evenly spaced spirals. Under the dark field microscope, it shows a characteristic motility, rotating on its long axis and moving slowly backward and forward. For clinical diagnosis it can be demonstrated by dark field microscopy of material from primary or secondary lesions.

Syphilis is transmitted by the direct contact of moist infectious lesions with mucous membrane. The disease is spread during the first and second stages, primarily by sexual contact, although occasionally by kissing or biting.

Once the spirochete has entered the body, it spreads with great rapidity. It may be found in the lymph nodes before the chancre is visible, and soon it appears in the bloodstream as well. In about a third of the cases, its entrance into the central nervous system is reflected first by an increase in the number of cells in the spinal fluid and then by increase in protein, alteration of the colloidal solution, and positivity of the Wassermann reaction. The reaction in the spinal fluid becomes positive in a third of patients within the 1st year. It has been said that, if the reaction remains

negative during the first 3 or 5 years, it will continue to do so, and that this in turn indicates that neurosyphilis is not present and will not occur. Also, it has been learned that the more severe the reaction and the longer its duration, the worse is the prognosis. Thus far, these changes in the spinal fluid need not be accompanied by symptoms, a situation classified as asymptomatic neurosyphilis. In about one patient of three, however, symptoms do develop; these cases are called symptomatic neurosyphilis.

Meningovascular syphilis. Early in meningovascular syphilis, the invasion of the nervous system is marked by edema, cellular infiltration (particularly lymphocytic), increase of connective tissue, and formation of granulomas or gummas. These changes follow the various fissures of the central nervous system. They may invade the brain, cord, and nerves and cause symptoms and signs in profusion that come and go. None of the nerves arising from the brain or cord is safe from involvement. Fever is rare, and sometimes the signs are those of acute meningitis, though more often the course is chronic. Headache, of course, is very common. There may be choking of the disks, but, even so, a spinal puncture must be ventured to decide the issue.

Involvement of the ependyma may close the sylvian aqueduct and lead to hydrocephalus. The dura mater may become enormously thickened and then may constrict both nerves and cord, most commonly in the cervical region. Such a hypertrophic pachymeningitis results in pain, sensorimotor paralysis of the upper extremities, and spastic paraplegia of the lower extremities. Spinal puncture usually reveals obstruction of the subarachnoid pathways. Gummas, though rare, may form at any place and produce effects simulating those of a tumor of the cord or brain.

A disease exhibiting such vagaries may appear to be almost any organic disorder of the nervous system. Perhaps the most serious mistake that can be made—and that very easily—is to overlook the fact that meningovascular syphilis may simulate a psychoneurosis.

As the disease progresses, large and small vessels (particularly the arteries of the brain) may undergo paravascular cuffing, intimal changes, and closure, with results dependent on the part of the brain served by the affected vessel. The onset is usually strokelike; and there may be hemiplegia, aphasia, hemianopsia, bulbar symptoms, stupor, and convulsions. The spinal cord, too, may become infarcted, with resultant paraplegia and incontinence. Closure of the veins may occur and lead to myelomalacia. Therapy is as described for paresis.

Paresis (general paralysis of the insane or dementia paralytica). A psychosis caused by extensive spirochetal invasion of the brain, paresis alone at one time accounted for more than 10 per cent of all admissions to mental hospitals. On examining the brain, one finds that the meninges are thickened, opaque, and

adherent to the brain. The convolutions are usually atrophic, the ventricles dilated, and the ependyma granular in appearance. Microscopic examination shows the meninges to be infiltrated with lymphocytes, plasma cells, and fibroblasts. The vessels are usually cuffed with small round cells, and the architecture of the cortex has a windblown appearance. A very characteristic finding is that of metallic iron in vessel walls and microglial cells. The ganglion cells are severely involved and the glia is increased, especially the microglia that forms rod cells. The spirochetes are scattered throughout the tissue.

Paresis occurs in about 5 per cent of neurosyphilitics and usually becomes evident in patients between the ages of 30 and 50 years—some 5 to 15 years after the initial infection. It appears earlier in men than in women and affects them at least twice as often. The onset is insidious, evidenced by slight defects of memory and deterioration of personal appearance and conduct, with increasing irritability and fits of temper. There is a blunting of regard for social and moral conventions. The first overt impropriety may be the pouring of champagne into a lady's pocketbook or urinating on the street. The patient may become gay and extravagantly generous, he may become depressed and hypochondriacal, or he may sink gradually into an apathetic dementia. He may become paranoid, delirious, or merely somnolent. While these changes are in progress, there may be interspersed convulsions and strokes of various kinds. The illness may have an acute or chronic course, but without treatment it ordinarily lasts about 3 years. The final scene is one of intellectual dilapidation, immobility, and filth.

Although it is customary to describe five types of psychosis and paresis, different clinical manifestations usually develop at different times during the illness. The classic parietic psychosis is manifested by euphoria, overactivity, ideas of grandeur, and megalomania. Delusions of wealth, physical prowess, and the like are common in this form. Most often the psychosis is intermixed with paranoid ideation, depression, simple dementia, and neurasthenia characterized by a variety of vague complaints. Rarely, there may be convulsions and signs of localized brain involvement (Lissauer's general paralysis).

On neurological examination, the slurred, slovenly words issuing from the sagging and tremulous lips of a parietic at once attract attention. The pupils may be irregular and small or unequal, and they often show the Argyll-Robertson response. The tendon reflexes are usually increased; there may be cranial nerve palsy and signs of focal damage to the brain.

The findings in blood and spinal fluid are more persistently positive than in any other form of neurosyphilis. The Wassermann reaction in blood and spinal fluid is almost invariably positive. Lymphocytes and occasionally neutrophils are present; protein is increased, and Lange's curve is usually strongest in zone 1. The diagnosis is based on clinical signs; but

the blood and spinal fluid findings just described, even without other clinical evidence, justify anticipation of paresis, and the situation is often referred to as *paresis sine paresi*.

The differential diagnosis includes consideration of all of the usual causes of early dementia, brain tumor, Alzheimer's disease, and others.

Treatment with penicillin has become so effective that the previously favored arsenic, mercury, and fever are rarely used. Indeed, most patients receive sufficient penicillin or other antibiotics during their lifetime to protect them adequately against paresis. When used, penicillin is given in divided doses totaling 15 to 25 million units in one course.

Response to therapy depends on the amount of brain damage at the time of treatment. Unfortunately, in some cases the brain damage antedating treatment is so severe that hospitalization must be continued, even though the spirochetal infection is cured.

Tabes dorsalis. A disorder resulting from spinal cord changes caused by syphilis, tabes dorsalis was once among the most common diseases of the central nervous system, but now it is rare.

Pathological examination reveals profound degeneration of the posterior columns of the spinal cord and posterior roots, varying in amount and location.

Tabes develops in fewer than 10 per cent of neurosyphilitics. It affects men more often than women, and the symptoms and signs usually delay their appearance until 5 to 15 years after the initial infection. One of the earlier symptoms is lightning pains. Although not quite pathognomonic of tabes, it is so suggestive that its behavior merits consideration. Lightning pains may appear anywhere in the body, but they are much more common in the lower extremities and more characteristic if they occur at some distance from the joints. They tend to come in "showers," often on some dollar-sized spot that becomes sensitive to the slightest touch but not to heavy pressure. They may feel as though the area had been touched by a lighted cigarette, but they do not exceed seconds in duration. They may be linear streaks of pain that explode terminally, like a rocket. One physician who had tabes compared these to the flight of lightning bugs. Lightning pains may occur in diabetic neuritis, multiple sclerosis, and syringomyelia, sometimes without demonstrable cause.

Also common in tabes is girdle pain, which feels as though a belt had been drawn too tightly around the waistline or chest. Still another type of pain common to tabes is the gastric crisis. A midline epigastric or abdominal pain, it may be mild or gruesome in intensity. It begins abruptly, continues for hours, days, or weeks, and, if there are no additional complications such as gastric or duodenal ulcer, ends abruptly. The recovery seems instantaneous: immediately after the pain, the patient may be found sitting up ready to eat a banquet meal. During the crisis, the patient does not tolerate the lightest touch of a sheet on the abdo-

men but raises no objection to a fist sunk deeply into it. The gastric crisis may be attended or entirely replaced by nausea, and the patient then presents a most pathetic sight as he lies over the edge of the bed with a stream of saliva running out of his mouth from morning to night.

For years, either lightning pains or crises may constitute the whole symptomatology of the disease. Typical crises may occur in other bodily regions and are then called laryngeal, testicular, or rectal crises of neurosyphilis.

Blindness, caused by simple optic atrophy, may appear early or late in both tabes and paresis.

A common symptom is ataxia. The gait begins to be insecure, and the patient tends to improve it by making a greater effort. As he does not feel his tread to be firm, he puts down his heels with greater force. He keeps his eyes on his feet to prevent movement from becoming still more unsteady. If he is ordered to close his eyes while in the erect position, he at once commences to totter and to swing from side to side (Romberg's sign). The insecurity of his gait is often greater in the dark.

Frequently the joints are affected by painless swelling, hypermobility, and disintegration, producing the Charcot joint. Sensory impairment and trauma are conditions attending these developments, but there is doubt that such insults alone suffice to explain the arthropathy.

Trophic ulcers occur frequently in tabes, usually on the ball of the foot. Examination also reveals Argyll-Robertson pupils and an absence of tendon reflexes, most often in the lower extremities.

Disease of the posterior roots probably accounts for the involved pattern of sensory disturbance, one of the cardinal findings by which one may recognize tabes dorsalis. Appreciation of touch, pain, and temperature may be impaired, lost, or perverted individually or in various combinations. The distribution of these changes is segmental, the parts most commonly affected being the lower extremities, then the thorax and medial aspects of the upper extremities, and finally the face. A pin applied to a toe or to the dorsum of the foot may bring forth prompt acknowledgment of contact but only seconds later an appreciation of pain—not a bright pain but one that may be described as a lingering and sometimes repetitive burning sensation that may be referred to some entirely different location such as the opposite extremity. A series of sensations provoked by a few pin pricks may be so kaleidoscopic that the examination has to be interrupted until they subside. It is important that the chest be examined with care, since sensory changes here are particularly helpful in diagnosis but are often overlooked. The sensory loss may be so profound that a corsage inadvertently pinned directly to the breast may be worn throughout an evening of entertainment.

A patient having tabes is often exquisitely sensitive to changes in temperature, and the application of a

cold test object to the abdomen or to the back may all but send him to the floor. Appreciation of movements of the joints, especially the toes, may be difficult. In tabes this loss is often greater than the loss of appreciation of vibration. Sensitivity of deep structures is frequently impaired more profoundly than is sensitivity of the overlying skin. This dissociation is one of the most characteristic features of tabes and almost at once distinguishes it from polyneuritis, in which superficial sensation also may be impaired. Eyeballs, testes, and large nerves may be squeezed vigorously without eliciting discomfort, but care should be exercised in making these tests. A gastric ulcer may perforate or the appendix may rupture without any warning to the attending physician that a catastrophe is under way. The sphincters are often relaxed, and the finding of a cord bladder is common and diagnostic.

The diagnosis is dependent on the characteristic clinical pattern and the serological findings. Posterolateral sclerosis may mimic some of the clinical features, and lightning pains may occur in diabetic neuropathy; but neither of these possibilities represents a serious problem in diagnosis.

Treatment is the same as for paresis. Unfortunately, there is usually no reversal of the objective findings; patients often remain ataxic, with lightning pains that may be difficult if not impossible to control.

Taboparesis. Paresis and tabes are sometimes concurrent, a situation that has been called taboparesis. The findings and symptoms are as one might expect in a combination of these two conditions.

Congenital neurosyphilis. Tabes and paresis, singly or in conjunction, may follow congenitally acquired syphilis but differ little from their expression in adults. The juvenile variants usually appear between the ages of 9 and 16 years. As would be expected, the juvenile paretic is likely to present a simpler deteriorating deficiency than in either tabes or paresis. The stigmata of congenital lues, such as keratitis and Hutchinson's teeth, accentuate the picture of misery. Treatment is the same as that described for paresis.

Rickettsial Infection

Rocky Mountain spotted fever. Encountered throughout the United States and Canada, Rocky Mountain spotted fever is an acute febrile disease caused by infection with *Rickettsia rickettsii*, which is transmitted to man by various ticks.

Pathological changes are found in the skin, heart, lungs, and central nervous system. The brain is edematous, and petechial hemorrhages appear on it. The characteristic microscopic lesions are small, round nodules composed of elongated microglia, lymphocytes, and endothelial cells. In addition, minute areas of focal necrosis are common as the result of thrombosis of small arteries.

Neurological symptoms occur early and include delirium, coma, convulsions, opisthotonos, and mental

confusion. Diagnosis is based on the characteristic development of a rash on the extremities first and on other symptoms 4 to 6 days after exposure to ticks. Clinical distinction from typhus fever may be impossible. Final diagnosis is dependent on neutralization and complement fixation tests.

The mortality of the disease without specific antirickettsial therapy varies from 20 per cent to as high as a reported 80 per cent in some areas of the Rocky Mountains. Even in those patients who recover, residual damage to the central nervous system may be apparent for some months. Chlortetracycline (Aureomycin), chloramphenicol, and oxytetracycline (Terramycin) are effective against rickettsial infections. Sulfonamides enhance the growth of rickettsiae and are contraindicated.

Protozoal Infections

Toxoplasmosis. Infection with the protozoan *Toxoplasma gondii* causes toxoplasmosis. The infection occurs most commonly in utero and has a predilection for the brain and the eye.

The organisms invade the blood vessels in the nervous system and produce an inflammatory reaction. Miliary granulomas are found throughout the nervous system.

Symptoms in the newborn are inanition, convulsions, spasticity, and chorioretinitis. The presence of chorioretinitis with encephalitis and roentgenological evidence of calcification is usually sufficient for the diagnosis, which can be established by complement fixation and skin tests.

Most patients die in the first weeks after birth. Mental and neurological deficits persist in those who survive.

Trypanosomiasis. The African form of trypanosomiasis, African sleeping sickness, which is endemic in Africa, is an encephalitis due to infection by *Trypanosoma gambiense* or *Trypanosoma rhodesiense*, transmitted by the tsetse fly. A similar disease is present in South America (Chagas' disease).

The pathology is that of chronic meningoencephalitis. The incubation period is variable. The first stage of the disease is characterized by remitting fever, chronic adenitis, exanthemata, and asthenia. In the second stage, involvement of the central nervous system is manifested by tremor, incoordination, convulsions, paralysis, mental disturbance, somnolence, and usually death within a year, if treatment is not given.

The diagnosis is established by the demonstration of the organism in the blood, cerebrospinal fluid, or material obtained from a lymph node.

Pentavalent arsenical drugs are the therapeutic agents of choice.

Systemic Infections

Brain function is frequently impaired in overwhelming systemic infection, even though the infection does not primarily invade the brain itself. Such

an effect may arise from the toxins liberated by the infection, from the metabolic impairment caused by the infection or inanition secondary to it, from anoxia secondary to impairment of respiratory or cardiovascular function, or from allergic responses that may present as encephalitis, even though the primary infection is elsewhere in the body.

In the past, such complications developed frequently, and in the form called delirium they appeared as a state of extreme mental and motor excitement, often with confusion, illusions, and even hallucinations. This syndrome, which occurred commonly with pneumonia, typhoid, and other infectious diseases, has become much less common with the widespread use of specific antibiotic therapy.

Acute viral hepatitis. A closely related group of diseases caused by viruses and characterized by parenchymal disorders of the liver are known collectively as acute viral hepatitis.

Mental symptoms are frequent in these diseases. They result rarely from direct invasion of the brain by the virus, more commonly by secondary toxic or metabolic changes in the brain. These are frequently characterized by delirium, a flapping tremor, and, if the disease progresses, coma.

Diagnosis is based on the characteristic signs of acute liver disease and sometimes a characteristic electroencephalographic pattern.

Treatment is symptomatic.

Malaria. Involvement of the nervous system occurs in a few patients with malaria, most often with the malignant tertiary form caused by *Plasmodium falciparum*.

The cerebral symptoms arise from occlusion of capillaries by pigment-laden cells and parasites, with resultant petechial hemorrhages. Usually, these symptoms appear in the 2nd or 3rd week of the illness, but they may be the initial manifestation and frequently are cataclysmic in onset. The symptoms include headache, photophobia, convulsions, delirium, and coma. As one might expect in a serious, debilitating illness with cerebral involvement, psychic symptoms are also common. Examination may reveal nuchal rigidity, paralysis, and cranial nerve palsy.

The diagnosis of cerebral malaria is made from the appearance of cerebral symptoms and the identification of *Plasmodium falciparum* in the blood.

Intravenous administration of specific drugs for malaria is effective if begun at the onset of mental symptoms.

Acute disseminated encephalomyelitis. Cerebral changes occur as sequelae to many of the exanthematous diseases and to vaccination for some of these diseases.

The changes have been thought due to the specific virus that causes the diseases in question or to secondary infection by a nonspecific virus. In recent years, a third theory—that the brain changes are an

allergic encephalomyelitis caused by the infectious agent—has gained wide acceptance.

Acute disseminated encephalomyelitis occurs more commonly following measles (0.5 per cent of cases) than other diseases. When German measles occurs early in pregnancy, severe cerebral defects in the fetus may occur. Sometimes it is associated also with chickenpox, scarlet fever, smallpox, measles, and whooping cough and with vaccination against tetanus, rabies, and smallpox.

Grossly, the brain exhibits irregularly outlined, yellowish red, soft, opaque spots. Microscopically, the lesion consists of a thin-walled vessel surrounded by an almost circular zone of rarefied brain tissue. Axis cylinders are well preserved.

The signs and symptoms come on within a week of the rash. The patient, who typically has been improving, becomes drowsy and stuporous and may have convulsions. The meningeal involvement may be severe, with nuchal rigidity. The spinal fluid reveals pleocytosis, mainly lymphocytic, with increased amounts of protein and sugar. Approximately 10 per cent of the patients die; and of those who recover, 50 per cent or more have residua, including ataxia, mental deficit, and epilepsy.

The treatment is symptomatic.

Infectious Diseases of Undetermined Etiology

Epidemic encephalitis (encephalitis lethargica, Economo's disease). The entity known as epidemic encephalitis was pandemic throughout the world from 1915 to 1926. Hence it is of historical interest, though not clinically significant now. Perhaps its chief interest to psychiatry lies in the many bizarre clinical syndromes that followed the disorder and that, in retrospect, resemble closely the phenothiazine intoxications.

Although the etiological agent was never identified, it has been assumed that it was a virus. Gross examination of brains from acute cases revealed congestion with engorgement of the vessels. Microscopic examination showed widely disseminated focal areas of inflammation, with a predilection for the basal ganglia, midbrain, and hypothalamus. The most characteristic lesion consisted of a perivascular infiltrate made up of lymphocytes and plasma cells. The ganglion cells evidenced widespread changes.

In chronic cases the results of gross examination of the brain were often negative. Microscopic examination frequently disclosed atrophy and loss of pigmentation of the substantia nigra and diffuse and focal areas of gliosis.

During the acute stage of the illness, patients had fever. Most frequently they were somnolent, less frequently hyperkinetic. Ocular palsies were common symptoms. Recovery followed an acute stage, which persisted for several days to months; there then ensued an interval of days to years in which numerous

patients, though appearing well, had many complaints—the so-called pseudopsychoneurotic stage.

The third stage developed gradually in adults and was usually characterized by Parkinson's syndrome. In adolescents the syndrome was most frequently one of hyperkinesia with behavioral abnormalities, and in young children the defect was one of mental impairment. Although these were common sequelae, frequently other and more bizarre syndromes, often initially believed psychogenic in origin, were also present or were present alone initially. There were sometimes disorders in respiratory rhythm; oculogyric crises were observed, in which the eyes involuntarily turned upward, rendering vision impossible. Other involuntary motor syndromes were noted, particularly about the mouth, with involuntary tongue protrusion being especially distressing to the patient. Vegetative disorders, such as increased somnolence, obesity, and disorders of sweating, were also common.

The clinical course of the syndrome, once the third stage was reached, was progressive; death usually occurred in 3 to 5 years. Milder cases, however, produced no sequelae, and the patients remained well.

Treatment of the acute epidemic was supportive. Treatment of the sequelae was symptomatic, the usual medications for parkinsonism being employed with only moderate benefit.

Acute chorea (Sydenham's chorea). "This disorder is a kind of convulsion, which chiefly attacks children of both sexes, from 10 to 14 years of age." There has been little change in the description since Thomas Sydenham's report in 1685. Its cause and pathogenesis remain uncertain, but the patients frequently have, or have had, manifestations of acute rheumatic fever, and a common basis is assumed. No infective agent has ever been implicated as a primary cause.

Few pathological examinations have been made, since the mortality is low, and no specific pathological changes have been reported from such examinations. But nonspecific, often diffuse, changes have been noted, such as edema and congestion of the cerebral hemispheres, scattered cellular infiltration, and loss of neurons in the cortex, basal ganglia, and cerebellum. The majority of patients are between the ages of 5 and 15 years, and more females than males are affected. The most common initial manifestation is the gradual development of involuntary movements, so that at first the child appears restless and fidgety. The most important symptoms of the disorder are brief, involuntary motions resembling fragments of purposive movements. They become more prominent, especially in the upper limbs, but muscles of the trunk and lower limbs may be involved also, as well as muscles of the face, tongue, and jaw, the latter producing severe dysarthria and difficulty in swallowing. The movements are more severe with muscular

activity and with excitement. They improve with rest and quiet; they disappear during sleep.

Mental symptoms are common, although not always pronounced. Irritability, fretfulness, and mild insomnia are often seen. Less frequent are severe symptoms such as marked agitation, excitement, insomnia, confusion, and hallucinations. Manic psychosis may be simulated, but it can be ruled out by the presence of the choreic movements. There are no abnormalities of the cranial nerves of sensation or of the reflexes. The cerebrospinal fluid usually appears normal, although mild pleocytosis may be encountered. Mild, diffuse, nonspecific abnormalities may be observed in the electroencephalogram.

The patients usually recover completely in 6 weeks to 3 months, and mortality is low (2 per cent). Recurrence may develop in approximately a third of the cases, especially during pregnancy. No sequelae are seen.

There is no specific treatment. In view of the self-limited nature of this disorder, supportive therapy suffices. The patient should be kept quiet and isolated from environmental stresses. Sedatives such as phenobarbital, paraldehyde, and phenothiazines may be very helpful in more severe cases, where the movements threaten to become exhausting or where agitation and confusion are prominent.

General Symptomatic Management of Brain Syndromes with Infection.

The management of brain syndromes accompanying infection is for the most part the management of the specific infection. The symptomatic treatment is not unlike that for other acute and chronic brain syndromes.

The preservation of a familiar and simple environment for the patient is important, as it is in all cases of brain impairment. This may be particularly difficult for the patient acutely ill with an infectious disease that necessitates isolation and the use of complicated and sometimes frightening medical equipment. It is therefore important to use as few persons as practical in providing adequate medical care. The patient should not be left alone, and the persons with him should maintain a reassuring and informative attitude. When possible, a few close members of the family should remain in close contact with him to assist in preserving contact with reality.

The physician should remember that the patient, because of his illness, is often unable to report frightening or anxiety-provoking symptoms. Patients with meningitis frequently have severe headache, and this may be relieved partially by 600 mg. (10 grains) of aspirin or Empirin compound (150 mg. of phenacetin, 210 mg. of aspirin, and 30 mg. of caffeine) with 30 mg. of codeine not more often than every 4 hours. Morphine and other similar analgesics must be avoided because of their depressant effect on cerebral function.

In other cases, as in bulbar polio, unrecognized anoxia may cause anxiety. Until the patient is placed in a respirator, it is impossible to control his anxiety and restlessness adequately.

If these measures are not sufficient to control restlessness and delirium, the physician may prescribe sedatives. This must be only a last resort, however; sedation often adds to the patient's disorientation and further depresses his respiration. If sedation is necessary, paraldehyde is the drug of choice, for it can be given orally, parenterally, or rectally and is seldom continued when not necessary. The dose varies from 5 to 10 ml. in adults and may be repeated. Similarly, amobarbital may be given intravenously in doses of 100 to 300 mg. But use of all such drugs should be avoided as much as possible in cases of acute infection.

For the chronic brain syndromes that are secondary to infections, symptomatic treatment is not very dissimilar to that for other chronic brain syndromes. Five to 20 mg. of methylphenidate (Ritalin) three times daily may be used in some cases of brain injury, particularly those marked by drowsiness or postencephalitic syndrome. Anticonvulsants such as diphenylhydantoin (Dilantin), phenobarbital, and primidone (Mysoline) are indicated in convulsive disorders. If the patient has postencephalitic parkinsonism, he should be treated with the usual specific drugs and in rare instances with surgery. Finally, the anxious and disturbed patient may be treated with one of the phenothiazine drugs, such as chlorpromazine, in doses of from 10 to 50 mg. three times daily; or other sedative drugs may be used.

20.4 BRAIN SYNDROMES ASSOCIATED WITH INTRACRANIAL NEOPLASM

RAYMOND W. WAGGONER, M.D.,
Sc.D.

Brain Tumor

In general, the term "brain tumor" is used to designate any intracranial new growth. It includes tumors involving the brain substance, the meninges, the ventricular system (including the choroid plexus), the pineal gland, and the pituitary gland. It also includes metastatic lesions within the intracranial cavity arising from malignancy elsewhere in the body.

The clinical manifestations of such neoplasms depend on a number of factors: the type and rapidity of growth, the location of the tumor, and its tendency to increase intracranial pressure. Thus, for example, a slowly growing tumor involving the frontal area is likely to produce much less increase in intracranial pressure and less apparent clinical manifestations than a much smaller neoplasm that obstructs the flow of cerebral spinal fluid from the ventricular system. Slowly growing tumors involving the silent areas of the brain, such as the frontal lobes, may be present for long periods of time without diagnostic symptomatology. On the other hand, if the neoplasm involves areas such as the motor cortex, focal manifestations may appear early in the course of the disease. For some reason not clearly understood, most intracranial neoplasms in adults arise above the tentorium, while most tumors in children arise below the tentorium. (See Table I.)

Types. Many different types of tumor are found in the cranial cavity. On occasion, the symptoms of such lesions may be primarily mental. It is important to keep this possibility in mind in all psychiatric patients, particularly if the history or findings presented by the patient are at all suggestive of such a lesion. It is common for such a diagnosis to be overlooked until the lesion is not susceptible to operative treatment. There are many different kinds of brain tumor, both malignant and benign, but a benign tumor in an inaccessible area may have as poor a prognosis as a malignant neoplasm. (See Figure 1.)

Gliomas. Gliomas represent the most frequent type

of tumor, with an incidence of approximately one third of all brain tumors. They are generally infiltrated. Some gliomas, such as the glioblastoma multiforme, spongioblastoma polare, and the medulloblastoma, are rapidly growing and have in general a very poor prognosis. On the other hand, the astrocytomas tend to be less rapidly growing and less malignant.

Metastatic carcinomas. The second group of infiltrating neoplasms are the metastatic carcinomas, which account for approximately 20 per cent of cerebral neoplasms. The prognosis in such cases is poor.

Meningiomas. A third group of neoplasms, the meningiomas, also represent about 20 per cent of all cerebral neoplasms. As a group, they can be considered the least malignant of all brain tumors. Since they may occur in almost any area of the brain, they are frequently overlooked as a source of psychiatric symptoms. Although the various types of gliomas and the metastatic carcinomas are primarily infiltrating, the meningiomas are not. The name of this neoplasm indicates its origin, although they may be found deep in the cerebral substance without apparent attachment to the meninges.

Manifestations. The manifestations of most acute and chronic brain syndromes are so positively colored by the premorbid personality of the individual that it is an impossible task to formulate a clear cut diagnostic categorization for most such syndromes. There are manifestations of brain tumor and other diseases involving the brain that are commonly and properly interpreted as being evidence of an organic brain syndrome. Inevitably, some of these changes are present, and in many instances they all appear. When the changes are the result of brain damage from which the patient cannot recover, the conditions are described as chronic.

Early signs. One of the earliest manifestations of organic brain syndrome is loss of memory, particularly recent memory loss. This is also characteristic of beginning senile changes. Next in order of usual appearance is disturbance in degree and quality of the patient's affective reaction. In the chronic syndrome particularly, this may develop gradually and not be readily recognized. It is associated with increased irritability and an increase in affective lability, and in brain tumor it is frequently associated with depression. Progressive loss of judgment, intellectual deterioration, and disorientation may be the next manifestations. Such changes are common in most organic brain syndromes and are not specifically diagnostic of the cause or type of difficulty.

In infants and very young children, increase in head size may be one of the first manifestations of brain tumor. In childhood, headache, disturbances in vision, clumsiness, and episodes of vomiting may signal the presence of such a lesion. In adult life, headaches, disturbance of vision, and the development of focal phenomena—such as irritative manifestations, Jacksonian attacks, generalized convulsions, and sensory

FIGURE 1. Simplified schema of the derivation of nervous system tissues and tumors. (Courtesy of S. P. Hicks, M.D.)

and motor changes—may be the earliest evidence of the development of an intracranial neoplasm.

Psychiatric symptoms. In association with the characteristic organic findings, there is usually a change in personality response that, in effect, is an exaggeration of the premorbid personality pattern. In brain tumor, the onset of such symptoms may be abrupt or gradual. Furthermore, wide variations in the psychiatric symptoms may be manifest. The following case is an example of this.

A 54-year-old white female appeared well until she had an abrupt episode of delirium, which lasted for only about 24 hours. After this episode there were progressive and more marked personality changes that were associated with a persistent depression and evidence of marked dependency. During a period of about 10 months these symptoms steadily increased, but the patient complained of no headache. The depression became quite severe. She was then admitted to a hospital for a complete evaluation. The physical and neurological examinations were reported as being within normal limits. However, a routine pre-electroshock electroencephalogram (EEG) revealed a right-sided focus, which was substantiated by a second localizing EEG. (See Figure 2.)

The EEG findings suggested an infiltrating neoplasm involving the temporo-frontal area, with the possibility of parasagittal or a deep extension. The focal slow waves were frequent and of a 1½ to 2 per second or a 3 to 5 per second type. They were seen in the right temporal region almost continuously, with a variable spread to the right frontal and parietal areas. Repeated neurological studies were reported negative, and the diagnosis of a convulsive disorder was suggested. A radioactive iodine uptake study was also reported as negative, the ophthalmological examination showed normal fundi, and, although the visual fields showed some contraction, they were interpreted as being evidence of an emotional disorder. Kahn test was negative, spinal fluid pressure was 150 mm., with a total protein of 150 mg. colloidal gold 00122200000, and a mastic of 123 321, but there was 4 plus globulin; x-ray of the skull was reported as negative. Because of the marked depression, which it was felt might lead to suicide, and because of negative evidence of a neurological lesion with the exception of the EEG finding, it was decided to treat the patient by electroshock therapy. Following the third treatment, the patient developed a left facial paresis, with weakness of the left arm and leg and increased confusion. An arteriogram revealed evidence of a right temporo-parietal lesion. On operation, a large degenerating glioblastoma multiforme was found infiltrating the frontal, temporal, and parietal region.

This patient gave a characteristic picture of a combined functional and organic brain syndrome, and with repeated negative neurological examinations and

TABLE I
Various Brain Tumors and Some of Their Characteristics

Tumor Type	Average Percentage of All Brain Tumors	Usual Age	Relative Prognosis	Usual Area Involved	Usual Presenting Symptoms	Onset and Type of Growth	Symptoms	Neurological Findings	Tendency to Recur
Gliomas									
Astrocytoma	14.0	Adults but may occur at any age	Fair	Adults in cerebrum, children in cerebellum	Focal brain symptoms	Slow, insidious	Headache, weakness, sensory disturbance	Motor and sensory changes dependent on location of neoplasm. Papilledema and visual field change may occur	Usual
Glioblastoma multiforme	12.0	Young adults, may occur at any age	Poor	Cerebrum	Headache	Rapid	May resemble symptoms of vascular accident	Papilledema. Motor and sensory changes dependent on location of lesion. Hemiparesis may occur suddenly from hemorrhage in neoplasm	Usual
Medulloblastoma	4.0	Usually children; may occur in adults	Poor	Cerebellum	Headache	Early rapid	Headache, visual disturbances, vomiting	Incoordination, clonus, staggering gait, dysmetria and dyssynergia. Tendon reflexes decreased. Pyramidal signs not likely to be present	Usual
Ependymoma	2.0	Adults	Poor to fair	Cerebrum and cerebellum	Neck pain or headache	Slow	Depends on location of neoplasm	Depends on location of neoplasm	Quite often
Astroblastoma	1.5	Children and adults	Poor to fair	Usually cerebrum, sometimes cerebellum	Varied	Slow but may be quite fast	Varied, especially with relation to location	Varied, especially with relation to location	Frequent
Oligodendroglioma	1.4	Adults	Poor to fair	Usually cerebral lumen	Convulsive attacks	Slow	Convulsive attacks, headaches	Depends on location	
Other gliomas	1.5								
Meningioma	19.0	Usually in adults	Good	Cerebrum	Dependent on location	Slow	Headache, confusion, depression	Depends on location	Rare
Metastatic carcinoma	17.0	Usually in adults	Poor	Cerebrum and cerebellum	Dependent on location	Fairly fast	Dependent on location	Depends on location	Usual
Pituitary adenomas	10.0	More commonly adults; may occur in children	Fair	Pituitary fossa	Visual difficulty	Slow	Headache, vomiting	Visual defects	Quite often
Others	17.6								

essentially negative ophthalmological studies, particularly without papilledema, it is not difficult to understand why the diagnosis of an intracranial neoplasm was overlooked.

The type of symptomatology depends to some extent on the location of the lesion, the kind of lesion, and the rapidity of its development. When the lesion is a slowly growing, compressing neoplasm such as meningioma in a relatively silent area of the brain, it may attain considerable size before evidence of increased intracranial pressure and other manifestations of a cerebral neoplasm are apparent. On the other hand, such a lesion may result in a clear cut affective reaction, as is exemplified by the following case.

A 52-year-old housewife was admitted with a history of recurrent episodes of depression of sufficient severity to require hospitalization. The original onset was characterized by a period of several weeks of severe frontal headache, for which no cause could be found and which disappeared with the onset of the first depressive episode. The depressive episodes varied in length from a few weeks to 2 months. With the fourth episode in 5 years, the patient began to demonstrate evidence of increased intracranial pressure. A neurological examination suggested the presence of right frontal neoplasm. A large right frontoparietal meningioma was found. After removal of the neoplasm, the mental symptoms disappeared and did not recur. Thus, the mental symptoms appear to have been definitely correlated with the presence of cerebral neoplasm.

A careful statistical study of 326 cases of supratentorial neoplasm, excluding metastatic lesions, was carried out at the University of Michigan. The study was designed to reveal the interrelationships among the following variables: mental changes, seizures, increased intracranial pressure, and the type and location of the neoplasm. Postmortem studies were available in 62 cases. The study revealed that mental changes were present in more than 58 per cent of the entire series. The mental changes did not appear to be influenced by the presence or absence of increased intracranial pressure. Similarly, such changes did not seem to be clearly related to the location of the tumor, although there appeared to be a trend toward more mental changes in those with frontal, temporal, and deep-seated neoplasms than in those with tumors involving the parietal or occipital lobe. Mental changes appeared to occur more frequently in cases of glioblastoma multiforme.

Seizures occurred in 48 per cent of the total series and were seen more often in the slowly growing and less malignant tumors than in the more malignant. Disorientation occurred in 39 of these patients, confusion in 59, psychotic behavior in 10, cognitive impairment in 77, affective lability in 15, lethargy in 41, personality changes in 46, depression in 12, euphoria in 5, decrease of attention span in 4, but an organic brain syndrome was diagnosed in only 11 patients. The changes as described were insidious and covered a period varying from a few weeks to many months. The personality changes tended to be an accentuation of the premorbid personality characteristics of the pa-

FIGURE 2. EEG findings in a 54-year-old woman. It shows frequent focal δ wave bursts (1.5 to 3 per second) in the right temporo-frontal sector (underlined strips), indicating the presence of a focal lesion. A malignant neoplasm was considered likely. Corresponding areas in left hemisphere (strips not underlined) do not show such focal waves. EEG first directed attention to this focal condition. By history and examination no neoplasm was suspected in this patient, whose only symptom was personality change, particularly profound depression. (Courtesy of R. W. Waggoner, M.D.)

tient. Such a finding is frequent in both chronic acute organic brain syndromes.

Of the glioblastoma group of patients, 71 per cent showed some kind of mental change; in the astrocytoma and oligodendroglioma group, only 53 per cent showed mental change; in the meningioma and pituitary neoplasm group, approximately 52 per cent showed mental changes; and in the cranial pharyngioma group, only 30 per cent showed mental changes. This study significantly emphasized the need for constant awareness that a neoplasm may be camouflaged by the presence of psychiatric manifestations. Interestingly enough, this study showed a relatively small percentage of a clear cut organic brain syndrome type of reaction, fewer than one would anticipate.

Selecki reported on a study of 10 mental patients with mental hospitalization and with symptoms of from 1 month to 5 years duration, and an age range of from 38 to 68 years. The 10 patients were divided into three groups. In the first group were those with frontocallosoal and anterior parietal neoplasms and those who showed such symptoms as alcoholism, progressive loss of recent memory, loss of insight and interest, depression, vagabond type of behavior, self-neglect, loss of planning ability, irresponsibility, and various other manifestations. Early diagnosis in these cases varied from chronic alcoholism and presenile dementia to psychopathic personality, epilepsy, and cerebral vascular disease. There were also symptoms such as dementia, perseveration, incontinence, drowsiness, disorientation, confusion, hallucinations and delusions, stupor, and mutism. Three of the 5 patients had glioblastoma, 1 had an astrocytoma, and 1 had an oligodendroglioma.

The second group had lesions involving the midportion of the corpus callosum, the bilateral posterior frontal area, and basal ganglia. The 2 patients had severe convulsive seizures, memory loss, loss of insight, and depression. They had only nondiagnostic neurological changes, with some vascular involvement. One neoplasm was an oligodendroglioma, the other an astrocytoma. These 2 patients were originally misdiagnosed as hysteria.

In the third group—with tumors involving the splenium, the posterior third ventricle, and the thalamic area bilaterally—the chief complaint was of attacks of rage and violence, failing memory, personality change, confusion, disorientation, dementia, and headache. Of these 3 patients, 1 was misdiagnosed as having Alzheimer's disease and another as having cerebral vascular disease. In this group, the neoplasms were glioblastoma multiforme, astrocytoma, and secondary lymphosarcoma.

Sinsh stated that psychiatric symptoms may be one of the more common modes of presentation of intracranial tumors and emphasized that this fact is often overlooked until the relationship becomes only too obvious. He suggested that the reactions in the early stages are primarily determined by the personality of the patient; in the later stages, manifestations are increasingly organic in nature. The clinical features in his opinion are dependent on the type and rapidity of growth of the neoplasm and on the degree of intracranial hypertension. Three of the patients in his series were given electroshock therapy. One of the three seemed to be improved, and the other two were made worse by such treatment.

Bilikiewicz and Grofska concluded that mental symptoms as manifested by temporal lobe tumors are not diagnostic but that such patients are more likely to manifest convulsive disorders of some sort. In 18 patients with temporal lobe tumor, only 3 manifested what they considered to be significant and typical symptoms.

It appears that mental symptoms of such specific order rarely occur, and their use as a diagnostic aid is not warranted. Confusion, disorientation, and hallucinatory manifestations can and frequently do occur in association with neoplasms involving the corpus callosum. Personality changes, particularly the kind of silly euphoria described as *Witzelsucht*, are frequently seen in tumors of the frontal lobe.

Karlyn et al. report that patients with space-occupying lesions involving the nondominant hemisphere have less intellectual deficit than patients who have lesions in the dominant hemisphere. The reason for this is obvious, and such results are to be expected. However, more evidence for such a conclusion is required before a definitive statement of this sort can be made.

Louis and Hirschenfang, in a study of supratentorial glioblastomas and meningiomas, pointed out that mental changes occur with tumors in all regions but are most common as initial symptoms of tumors of the

prefrontal region with or without involvement of the corpus callosum. Headache, however, is the most frequent presenting symptom. Mental changes were also considered more likely to be found in infiltrating tumors than in extrinsic compressive lesions, such as meningiomas.

Mental and psychiatric symptoms appear to occur with tumors involving any part of the brain, including the infratentorial area. These symptoms tend to be of the organic brain syndrome type, with reduction in intellectual capacity, loss of memory, confusion, delusions, hallucinations, etc. The mental symptoms resulting from a neoplasm in any given area, however, do not produce characteristic psychiatric symptoms, nor is it possible to consider such symptoms significant in making a differential diagnosis of the tumor type, although infiltrating neoplasms seem to produce more mental symptoms than noninfiltrating lesions.

Diagnosis. The diagnosis of brain tumor is often difficult but rarely more perplexing than when the presenting symptoms are primarily psychiatric in nature. The occasional brain tumor found in autopsy in a patient who has been hospitalized for years in a state mental hospital should serve as a warning that brain tumors may occur even when the only manifestation is that of psychopathology. Early in the development of a cerebral neoplasm, such a diagnosis can be overlooked by the most astute observer. That such conditions may occur as a coincidental manifestation but with a neoplasm as the source of psychiatric symptomatology should always be kept in mind. Every patient should have a careful neurological evaluation and such other studies as may be indicated to make sure that a neoplasm is not being overlooked. Statistical studies in various state hospital populations indicate that cerebral neoplasms may occur as much as three times more frequently than in the average population. However, other studies have shown no greater incidence than in nonpsychiatric hospital groups.

When the history and neurological findings indicate the presence of a possible intracranial neoplasm, various diagnostic studies should be undertaken. Of primary importance is a series of x-rays of the skull, which may demonstrate evidence of intracranial pressure and indicate the position of the lesion. A careful study of the eye grounds and of the visual fields should be made. If evidence of increased intracranial pressure, as demonstrated by papilledema, is present, a lumbar puncture should not usually be done. The electroencephalogram, brain scan, and arteriography are indicated in such instances. As a final preoperative diagnostic procedure, the neurosurgeon may want to do a ventriculogram, although this may not be of help in the early phase of a brain tumor.

In the final analysis, neurological findings and special diagnostic procedures such as the brain scan, arteriogram, and the electroencephalogram must be used in order to make an accurate diagnosis. It is possible to have mental symptoms as the presenting feature of

the organic brain syndrome associated with brain tumor, and such symptoms may persist over a period of months or even years with little evidence of increased intracranial pressure or other characteristic or localizing signs of cerebral neoplasm.

In the differential diagnosis of cerebral neoplasm, one should consider the possibility of brain abscess, subdural hematoma, focal meningeal cyst (particularly an arachnoiditis), cerebral arteriosclerosis, vascular malformations, subarachnoid hemorrhage, meningitis, and encephalitis.

Prognosis. The prognosis of brain tumor depends primarily on two factors: the malignancy of the neoplasm itself and its location. The more malignant the neoplasm, such as the glioblastoma or medulloblastoma, the poorer the prognosis, irrespective of the location of the tumor. On the other hand, slowly growing tumors, such as a meningioma, have a relatively good prognosis, while an astrocytoma has a fair prognosis, unless it is inaccessible to surgery.

Treatment. The treatment of brain tumor depends almost entirely on the possibility of neurosurgical intervention. The earlier the diagnosis and the more accessible the lesion, the better the results of treatment. Error in diagnosis may lead to treatment procedures, such as electroshock therapy, that may be harmful to the patient. Control of psychiatric symptoms after diagnosis, both pre- and postoperatively, should be through the use of the phenothiazine compounds with which the therapist is most familiar. Care should be exercised to avoid overdosage, and the patient should be constantly observed for possible side effects, such as symptoms resembling paralysis agitans.

Subdural Hematoma

Etiology. In almost every instance, the cause of subdural hematoma is trauma, although in a surprisingly large number of cases it is not possible to obtain such a history. Other conditions may also result in this syndrome. Various types of blood disease and infectious disease have been considered as a causative factor.

Possible causes of psychiatric symptoms. A study by Rubert and Remington emphasized the need for constant awareness of the possibility of brain tumor as the cause of thinking disturbances. They pointed out that the origin of psychological symptoms of tumor patients is not well understood but suggested four alternate explanations: (1) A tumor may exist coincidentally with a psychosis. They reported that surveys have indicated that patients in psychiatric hospitals have about the same incidence of brain tumors as the general population. (2) The symptoms of a psychiatric syndrome may be caused directly by the tumor itself, and it may be of an organic or functional nature. It is reasonable to assume, and evidence seems to indicate, they concluded, that an expanding lesion can cause nonspecific manifestations

of brain damage, similar to those of other organic brain changes. Organic brain symptoms as manifested by loss of cognitive capacity and associated memory loss with impairment of abstract thinking and lowered attention are relatively common. Some authors have insisted that the syndrome of a functional nature could not be simulated by neoplasm. This does not appear to be an acceptable hypothesis, since the psychiatric manifestations in some cases disappear and remain absent after neoplasm removal. (3) A depression may occur secondary to the patient's awareness of his intellectual loss as a result of neoplasm. Since the neurological manifestations may be intermittent, the mental symptoms may also be intermittent under such circumstances. (4) Patients with brain tumors may develop psychiatric symptoms because of the way they are treated by other people when their organic deficit becomes apparent. The authors pointed out that the senile patient becomes emotionally disturbed if too much is demanded of him. Similarly, the patient whose brain is damaged by a neoplasm may become upset emotionally if his intellectual limitations are not understood by those with whom he associates.

Manifestations. In the acute form, blood collects beneath the surface of the dura, and there may be an associated subarachnoid or extradural hemorrhage. The subacute form represents a transition phase to the chronic form, in which there is a collection of fluid in a cystlike formation or organized clot, with the development of a membrane that encloses the fluid or clot. This collection of fluid or clot causes pressure on the brain and produces evidence of increased intracranial pressure, with signs and symptoms dependent on the area involved. After trauma there may be a short period of headache and perhaps dizziness and confusion, followed by a symptom-free period of days to months before the manifestations of the chronic state occur. The first manifestations are usually mild and subjective, such as headache and dizziness. These symptoms may then be followed by the more severe signs, such as those commonly found in the organic brain syndrome. Evidence of increased intracranial pressure is usually present, manifested by papilledema and cerebrospinal fluid hypertension. However, the mental symptoms may be the only significant clue to the pathologic process.

There are numerous reports in the literature of mental symptoms associated with subdural hematoma. Mateos and Daly, in an analysis of 123 cases, with 85 per cent of the patients in the 20 to 60 age group, stated that frequently the first indication of a subdural hematoma is the change in personality as observed by the patient's associates. These changes are essentially those of an organic brain syndrome—confusion, impaired memory, and bizarre behavior. The possibility of a subdural hematoma should not be overlooked in the presence of such symptoms. Most reports in the literature indicate that a high percent-

age of patients with subdural hematoma show some kind of mental abnormality, which may vary from mild personality changes to frank psychosis.

As in many other types of brain lesions that produce an organic brain syndrome, the chronic subdural hematoma may produce a host of different kinds of psychiatric symptoms. Such symptoms as hyperactivity, depression in intellectual function, memory deficit, temporal and spatial disorientation, and indifference to moral attributes have been described. Some authors have even reported that all patients with subdural hematoma show some mental changes ranging from a mild disturbance in abstract thinking in some cases to significant disorientation in others. It is particularly important to consider subdural hematoma in the differential diagnosis in patients who may be brought to the hospital in a coma where there is evidence of alcohol consumption. Johnson and Sinkler emphasized that too often both professional and nonprofessional people attribute coma, a clouded sensorium, or mental confusion to alcohol alone and that subsequent studies prove the existence of a subdural hematoma. Johnson and Sinkler pointed out that the chronic subdural hematoma may present a picture of psychosis, of degenerative neurological disease, or the symptoms of a brain tumor. Such manifestations may develop gradually over a considerable period of time, with the early symptoms being those of irritability, somnolence, lethargy, and personality change.

Since both acute and chronic subdural hematoma may result from a relatively mild injury that may not be recalled either by the patient or by his family and since in a large number of patients there is a complaint of headache, the possible presence of a subdural hematoma should be kept in mind. Symptoms of a subdural hematoma may fluctuate considerably and thus may render the diagnosis that much more uncertain. This is particularly true in the older patient, who may be particularly susceptible to the development of a subdural hematoma and in whom the organic brain syndrome associated with senile changes are to be expected, thus tending to camouflage the existence of the hematoma. Many patients with a subdural hematoma are first seen by a psychiatrist because of the severe mental changes that may lead to a diagnosis of senile dementia or of various other psychiatric syndromes. Often there is wide variation in symptoms, which may be inconstant and sometimes contradictory.

Gomez, in a study of 100 cases of subdural hematoma over a period of 25 years at one hospital, could find a history of trauma in only 71 of these cases. Headache was the most frequent symptom in the subacute and chronic cases, with 93.9 per cent of the patients having this complaint. The author states that mental confusion, drowsiness, and a fluctuating level of consciousness was found in almost every case. Thus, mental confusion, particularly with increasing drowsiness either intermittent or continuous, ap-

pears to be a most important diagnostic symptom of the chronic subdural hematoma.

Differential diagnosis. Some authors have classified subdural hematoma into three groups: (1) the acute, which occurs up to 2 days after the onset of symptoms, (2) the subacute, with a period of from 2 days to 2 weeks, and (3) the chronic, if there is a history of more than 2 weeks subsequent to the onset of symptoms or to the head injury.

In acute subdural hematoma, there is invariably a history of injury immediately preceding the development of symptoms. In such cases, there is usually a marked degree of loss of consciousness, increased intracranial pressure, dilation of the pupil on the side of the lesion, and partial or complete paralysis on the side opposite the lesion. It is often difficult to differentiate the acute subdural hematoma from that of subarachnoid hemorrhage.

In the subacute form, which some authors classify with the acute form, the diagnosis is perhaps less difficult, although there may be considerable variation in symptomatology, since the patient may experience varying levels of consciousness with confusion and somnolence over a period of 2 or 3 weeks. In the early acute cases, almost invariably there is blood in the spinal fluid, but in the subacute cases, the spinal fluid may be xanthochromic. In some instances, in the acute and subacute form, evidence of acute alcoholism may cloud the differential diagnosis.

In chronic subdural hematoma, in addition to the psychiatric symptoms described above, there are frequently episodes of headache and dizziness, which may be associated with episodes of unconsciousness. There may be signs of progressively increasing intracranial pressure. Since the symptoms may depend to a large extent the location of the hemorrhage, it is often difficult to differentiate the chronic subdural hemorrhage from brain tumor. The primary diagnostic differentiation from brain tumor is the history, if obtainable, of a previous trauma to the head.

Prognosis and treatment. Properly treated, the prognosis of subdural hematoma is quite good. The treatment of this condition is always surgical, but there is still considerable discussion of which surgical method will give the best results. Furthermore, the treatment must necessarily vary in accordance with the maturity of the lesions, which are either acute, subacute, or chronic.

Brain Abscess

Although the incidence of brain abscess is much less now than it was before the development of antibiotic and anti-infective chemotherapy, it still represents a condition that must be considered in the differential diagnosis of the various conditions presenting an organic brain syndrome. Since brain abscess is most commonly secondary to infection about the head and neck or elsewhere in the body, such infection gives a clue to the presence of brain abscess when the

symptoms indicate cerebral involvement. In a few instances, however, no primary source of infection may be found.

Manifestations. Abscess of the brain is a focal infection involving intracranial structures. It may occur either above or below the tentorium. The abscess usually begins as a localized encephalitis and, in most cases, becomes encapsulated within 10 days to 2 weeks. Evidence of meningeal irritation is often present, particularly in the early stages of the condition. In a large proportion of cases of brain abscess, it is the result of extension of the infection about the head. In only a small percentage of cases is it associated with trauma or does it occur as a result of the metastasis of infection from other areas of the body. With the onset of such cerebral symptoms in known infections of various paranasal sinuses or the mastoid process, the diagnosis is not particularly difficult. On the other hand, in patients with pulmonary infection, probably the most common cause of metastatic cerebral abscess, the diagnosis may be much more difficult.

In such cases and in those cases with a hidden infection, the first manifestation of brain involvement may be the development of somnolence, intellectual dulling, and confusion. This should suggest to the astute observer the possibility of brain abscess. The manifestation of abscess of the brain, secondary to infection elsewhere, may develop in a few hours or days, or the symptoms of an encapsulated abscess may become manifest many years after the original infection. The infection involves the brain most commonly by direct extension from sinus disease or by venous extension. It may also occur by more direct vascular transmission as, for example, secondary to pulmonary infection.

Although brain abscess may occur in almost any part of the brain, the frontal and temporal lobes and the cerebellum are the areas most commonly involved, since intracranial extension of an extracranial infection is most direct in these locations. Brain abscesses may be single, as in the case of direct extension of infection, or multiple, as is frequently seen in the metastasis of infection. With the exception of the evidence of infection, which is almost invariably present, and the somewhat peculiar mental state that so often occurs, the symptoms of brain abscess are like those of brain tumor. The symptoms depend to a considerable extent on the location and the degree of increase of intracranial pressure.

Relatively little comment about mental symptoms in patients with brain abscess can be found in the literature. It is certainly clear that brain abscess can produce mental symptoms like those of brain tumor. There are usually, however, other manifestations, such as increase of temperature, increase in white blood count, and evidence of preexisting infection, which gives a clue to the kind of cerebral lesion with which one is dealing.

Julien et al. reported an interesting case of a pa-

tient with an abscess of the right temporal lobe and with early signs of a pseudoencephalitis and with psychic symptoms. The symptoms manifested themselves paroxysmally, and there was a sensation of *déjà vu*, dreamy state, micropsia, and macropsia. There were also auditory and olfactory hallucinations and disturbance in attention.

Irsiglar reported that in brain abscess, particularly in cases secondary to sinus infection, "striking changes in behavior or personality may be the first and, in fact, the only sign of a unilateral frontal abscess." In infections involving a paranasal sinus, he pointed out that personality changes may be diagnostic of unilateral extension into the anterior cranial cavity and that such mental changes may persist or even become worse after successful surgical intervention. It should be noted, however, that such personality disturbances, particularly of the acute organic brain type, may occur without direct brain involvement in association with systemic infection, thus increasing the diagnostic dilemma.

Loeser and Scheinberg, in a review of 99 cases of brain abscess, made no comment about the presence of any mental symptoms. Smith described the case of a boy of 12 who is said to have been normal and well behaved until he developed a fever and frontal headaches, which lasted for 2 days. Three months later, he began have difficulty in school because of his behavior, both toward his peers and toward his teachers. Subsequently, he developed larcenous habits. For a period of 2 or 3 months, the diagnosis of brain involvement was not made until he was admitted to a hospital, where it was found that he was mentally confused, emotionally wild, and unstable. There was marked fluctuation in his moods, from "surly stupor to maniacal viciousness." A diagnosis of frontal abscess was made. With treatment, he improved promptly. Within a few days, he was again a friendly, likable boy. The authors reported this as clear cut evidence that the mental symptomatology was secondary to the frontal lobe abscess.

The following case report illustrates the kind of symptoms and the difficulty in differential diagnosis that may be seen in brain abscess. As is so frequently the situation early in the development of brain abscess, the symptoms are by no means characteristic either of the location of the abscess or of the symptomatology of brain abscess in general.

A 57-year-old male was admitted to the hospital because of confusion, headache, and a possibility that he had had a stroke. There was a history of preexisting pansinusitis over a period of several weeks, inadequately treated by small doses of an antibiotic. Shortly after admission, there were two episodes of convulsive attacks. There was significant evidence of meningeal irritation and varying neurological findings of unilateral increased muscle tone of the spastic type, increase of tendon reflexes, and a Babinski's sign on the left. There was a left facial palsy and a spiking temperature to 103° F. Shortly after admission, the patient became unconscious. There was an increase in spinal fluid pressure as measured by lumbar puncture, with 100 white cells

per centimeter in the spinal fluid. Pneumococci were cultured from the spinal fluid. No focal abscess could be demonstrated by arteriogram or by brain scan. He was placed on large doses of antibiotics, and most symptoms disappeared in a few days, but there was some evidence of continuing organic brain syndrome, as manifested by mild confusion and memory loss for several weeks. It was considered likely that this patient had a diffuse brain abscess or a unilateral and focal pneumococcal encephalitis that responded to treatment before the abscess became encapsulated.

Differential diagnosis. In the differential diagnosis of brain abscess, one must consider brain tumor, meningitis, encephalitis, and lateral sinus thrombosis. In brain tumor there is rarely evidence of infection, but infection is invariably present in brain abscess before it has become encapsulated and relatively quiescent. The organic brain syndrome of either may be essentially the same, although in brain abscess there is apt to be more confusion and somnolence and more evidence of meningeal irritation than in tumor. In association with the mastoid infection, the differentiation from lateral sinus thrombosis may be very difficult. However, the spinal fluid in a case of sinus thrombosis is usually normal, and tenderness in the jugular vein area is present.

Prognosis and treatment. The prognosis in brain abscess is relatively good in most cases, particularly when the abscess is well encapsulated. The treatment before encapsulation is medical, with adequate amounts of antibiotics of the type to which the organism is susceptible when this can be determined. The treatment of the encapsulated abscess should be a combination of medical and surgical therapy.

Suggested Cross References

Further information regarding the neurological examination may be found in Chapter 10, on neurology. In that same chapter, brain tumors, subdural hematoma, and brain abscess are also discussed from a neurological perspective.

Chapter 21

Brain Disorders. IV: Associated with Convulsions (Epilepsy)

21.1 • • •

FRANK R. ERVIN, M.D.

Introduction and History

The air was filled with a big noise and I thought that it had engulfed me. I have really touched God. He came into me myself, yes God exists, I cried, and I don't remember anything else. You all, healthy people, he said, can't imagine the happiness which we epileptics feel during the second before our fit. Mahomet, in his Koran, said he had seen Paradise and had gone into it. All these stupid clever men are quite sure that he was a liar and a charlatan. But no, he did not lie, he really had been in Paradise during an attack of epilepsy; he was a victim of this disease like I was. I don't know if this felicity lasts for seconds, hours or months, but believe me, for all the joys that life may bring, I would not exchange this one.

Such descriptions by Dostoyevsky and by countless other writers, as much as the often cited tonic-clonic convulsion, cyanosis, stertorous breathing, salivation, and trance-like mumblings of postictal confusion, must have helped name epilepsy the "sacred disease." Certainly, from Hippocrates to the present, epilepsies have attracted attention and investigation far exceeding their numerical importance. This has been encouraged by the rewards resulting from meticulous observation of the neurological phenomena preceding and following the fit, analyses that have provided some of the clearest insights into human brain organization. In no other syndrome does nature duplicate so clearly the exploring electrode of the experimental neurophysiologist. In fact, there are few observations from experimental brain stimulation that have not, at least qualitatively, been previously delineated by an epileptic seizure.

In recent years, the experimental neurophysiologist has added to his interest in the mechanism of motor and sensory control those problems of complex behavior falling under rubrics like learning, motivation, and perception. Clinically, it is the psychiatrist who copes with disturbances in these areas. It seems likely

that thorough reexamination of the rich psychopathology of those patients with known structural or functional disturbances of cerebral organization, particularly of episodic occurrence, will help clinical psychiatry most effectively support, guide, and incorporate current advances in the laboratory. For instance, the intriguing phenomenon of self-stimulation of brain centers in the experimental animal and the questions it raises about motivation may well be illuminated by careful clinical investigation of those children and some few adults who self-stimulate their flicker-induced seizure state.

This section leaves untapped much of the neurological richness of the epileptic phenomena to concentrate on those behavioral aspects most pertinent to the psychiatric audience. For both neurology and psychiatry, epilepsy presents not only a challenging problem involving many millions of the world's people but a natural entree into the borderland between structure and function of the brain. Careful attention to its varied aspects should lead a step closer to resolution of the ancient dichotomy of mind and brain, which has impeded so much thinking and practice.

At the turn of the century, when Freud was elucidating the psychopathology of everyday life and suggesting the study of normal dreams as "the royal road to the unconscious," Hughlings Jackson was making his classic observations on the phenomena of epilepsy. Jackson was particularly attentive to the neurological insights to be gained, but he suggested that the "understanding of the dreamy states [of temporal lobe epilepsy] would be the key to the understanding of insanity."

Whether or not there is such a straightforward key, it is certainly true that there are few psychopathological phenomena that have not appeared as epileptic episodes. Disorders of affect, such as depression, anxiety, terror, and rage; disturbances of thought, such as forced thinking, obsessive rumination, fragmentation, and neologism; perceptual changes, such as hallucinations, depersonalization, *déjà vu*; and dis-

turbances of behavior, such as recurrent dreams, transvestitism, and ritual behavior—all have been described, particularly in relationship to temporal lobe epilepsy. More dramatically, the states of manic elation, delusional paranoias, and catatonic stupor or excitement have also been tied to seizure disorders.

These conditions pose some interesting diagnostic challenges. However, once the usual pragmatic dichotomy of organic versus functional has been made for purposes of instituting therapy and guessing at prognosis, it should be fruitful to erase that dichotomy and investigate the phenomena further. It may well be that the unique organization of neural systems necessary to produce depersonalization, for instance, is the same whether it is activated by a synchronous neural discharge from the hippocampus, by an overwhelming current life stress, or by some commonplace event to which the schizophrenic patient is uniquely sensitized. The clarification of such issues should be of inestimable value in arriving at optimal therapeutic procedures and in extending the understanding of psychopathology from the level of organization of psychological events to the level of neural events.

Unfortunately, most American psychiatrists have relinquished the clinical responsibility for the epileptic and thereby the opportunity to learn from him. At the same time, many neurologists have felt a concern only for achieving that level of medication necessary to subdue the abnormal electrical activity of a presumably static cerebral lesion; they have failed to take advantage of the plasticity of the nervous system in planning the management of the total individual with epilepsy or even of his specific symptoms. A dramatic insight into the possibilities in this direction is provided by an elegant study by Efron, who demonstrated that a conditioned reflex could be established by association to block the appearance of uncinate seizures in a young woman. A similar phenomenon was observed by Gowers some 80 years ago and apparently by Boettius in some cases of Jacksonian epilepsy as early as the 17th century. Though some experimental work has been attempted in recent years, there has been too little pursuit of either the theoretical or pragmatic aspects of this observation.

Definition

Strauss correctly observed that "a truly satisfactory definition of 'epilepsy' on the basis of clinical characteristics is nonexistent." No doubt there exist as many definitions of epilepsy as there are neurologists and as many types of epilepsy as there are patients. To encompass the diversity of the epilepsies, one can say little more than this: (epilepsy is that state of impaired brain function characterized by a recurrent, periodic, paroxysmal disturbance in mental function, with concomitant alterations in behavior or thought processes.) This generalization covers many disturbances not today believed to be epileptic and is thereby subject to criticism, but perhaps the sin

of overgeneralization will be pardoned more readily by future investigations than its antipode will be.

(Diagnosis)

In spite of the prevalence of epilepsy, and an abundance of literature discussing its diagnosis and treatment, it is shockingly handled by most physicians.

[A seizure of any kind is a symptom, not a disease. It is a symptom of brain dysfunction, either localized or general, and should be investigated as only one, even if the most dramatic, of a potential complex of signs and symptoms. That there is, on occasion, dysfunction of the brain is not surprising. The complexity of its interconnections, from the most simple-minded cybernetic point of view, ensures that uncontrolled oscillation will be one of the ways in which it can become disorganized. The marvel, as Walter once commented, is that seizures are not more common. The occurrence of a fit signals that the complex of neural, humoral, metabolic, and vascular regulatory systems of the brain are in imbalance.]

† **Non-neural pathophysiology.** The first diagnostic question to be asked is whether there exists treatable nonneural pathophysiology. Hypoglycemia, pyridoxine deficiency, eclampsia, uremia, anoxia, hyponatremia, water intoxication, and fever are all states that may lead to convulsions. In the same class should be mentioned seizures following withdrawal—usually abrupt—of a wide class of pharmacological agents, especially alcohol, barbiturates, meprobamate, diazepam, and anticonvulsants. Apparently, withdrawal seizures can follow any neuroactive drug on occasion.

Intracranial pathology. The above generalized metabolic disorders are mentioned first, since they are frequently accompanied by behavioral disturbance, perceptual or thought disorders, or frank psychosis and thus come to the attention of the psychiatrist. Etiologically more common are seizures following cerebrovascular hemorrhage or thrombosis. Indeed, they may be the symptom of onset in these conditions. Cerebral vascular disease is particularly to be suspected with seizures occurring for the first time in adults, particularly those past midlife. In these patients, structural intracranial pathology should be routinely suspected and vigorously excluded by adequate diagnostic procedures. Whether the pathology be neoplasm, vascular disease, vascular malformation, abscess, acute or chronic infection (such as syphilis, tuberculosis, and cysticercosis), or degenerative disease (such as Pick's and Alzheimer's), fits may be an early symptom and often important in localization.

Trauma. A more easily recognized but much abused cause is trauma. Post-traumatic epilepsy is an important and well studied problem.

The problem is that, in assiduous history taking, a large number of patients and families remember all

too clearly some recent or remote head injury, to which is attributed all subsequent misfunctions of the individual. To avoid this trap, the physician must sort out the relatively infrequent seizures following closed head injury and differentiate them from surgically treatable syndromes, especially chronic subdural hematoma.

Diagnostic work-up. The above outline of differential diagnostic problems, in which the focus of diagnosis and treatment is not on the seizure but on the etiological process, presumes the confirmed existence of a convulsion. Unfortunately, this presumption is not always justified; the physician may never see an episode in the patient who has only one or a few spells. One must, therefore, be wary and sure that the patient's loss of consciousness, abnormal motor movements, etc., are not due to other central nervous system malfunction. Syncope, Adams-Stokes syndrome, hypoglycemia, tetany, narcolepsy, catalepsy, breath holding, hysteria, and malingering are but a few of the varied syndromes that get misdiagnosed as epilepsy.

The above account suggests that before one settles down to classify and treat an epileptic, a careful diagnostic work-up is necessary. Minimally, a set of skull x-rays, lumbar puncture, blood serology, fasting blood sugar, brain scan, and electroencephalogram (EEG) should be added to a meticulous physical, neurological, and routine clinical laboratory examination and careful history, paying particular attention to recent drug intake. Any suggestive abnormalities should of course be pursued in depth with suitable procedures.

Hysterical and simulated seizures. Of particular interest in arriving at a differential diagnosis is the problem of hysterical or frankly simulated seizures. These may pose considerable difficulties, particularly when one suspects temporal lobe epilepsy with its frequently ambiguous EEG findings and unusual variety of seizure patterns.

The standard shibboleths for seizure diagnosis seem to include unconsciousness, tonic and clonic movement, loss of sphincter control, amnesia, and self-injury, such as bitten tongue and head injury from falling. This set of phenomena describes many grand mal seizures but is not a *sine qua non* for all epilepsies. Focal seizures, such as Jacksonian seizures, may not be accompanied by loss of consciousness unless the motor symptoms become bilateral. Some psychomotor patients may retain a hazy or distorted memory of the seizure period and may not appear unconscious to an observer. To further becloud the issue, a number of patients with a real seizure problem have also learned to use the seizure for secondary gain. They may learn ways of precipitating a fit—by hyperventilation, for instance—or they may simulate a fit. Recognition of the simulation by a professional observer may prejudice him against diagnosis of the

patient's coexisting epilepsy. In one such patient, his true seizures were due to a temporal tumor.

The least convincing pseudoseizures are those of the relatively unsophisticated hysteric. Here there is usually a clear life crisis precipitating the seizure, much exaggerated thrashing about without a clear pattern of motor involvement, and usually the possibility of interruption of the state by a patient examiner. There are no neurological signs—pupillary changes, Babinski responses, EEG abnormality, etc. (It has been suggested that a fair diagnosis of hysteria can be made by counting the number of people accompanying the patient to the emergency room.)

The deliberate malingerer may be more difficult to detect, as he may with practice become quite skillful in simulation. Here, the suspicion aroused by clear secondary gain and a thorough neurological examination with EEG at the time of seizure may be the only data on which to base a confrontation with the patient. The problem is psychiatrically no different from diagnosing and dealing with other malingerers.

Procedure. An individual reported to have abrupt, self-limited, recurrent alterations of sensation, behavior, or consciousness, especially with motor manifestations, should be suspected of having epilepsy. First, attention is directed to confirming the existence of a seizure. Second, one attempts to recognize pathological conditions to which the seizure is a secondary phenomenon, although, as a dangerous symptom, it may merit active anticonvulsant therapy in conjunction with specific therapy for the primary condition. Having excluded these conditions, one is left with an epileptic patient to be further categorized.

Classification

A traditional first division of the epilepsies is between the idiopathic or cryptogenic and the symptomatic or secondary seizures. With increasing emphasis on physiological mechanisms and electroclinical correlations, a more common current division is between the generalized or centrencephalic fits and focal seizures; focal seizures involving the temporal lobe are often separated out for special consideration (see Table I).

(The anatomical delineation of temporal lobe seizures is often used interchangeably with the more clinical description "psychomotor," although they are not identical.) Since the classic psychomotor seizures may have an anatomic and indeed an electrical focus in regions of the brain other than the temporal lobe, it seems quite likely that the temporal lobe structures are involved in these cases by secondary spread, but that is a physiological hypothesis that does not justify the confusion of terms. Unfortunately, the literature is, in general, so unclear on this distinction that the confusion will probably be perpetuated by this section when an attempt is made to compare clinical syndromes.

The categorization of an epileptic patient depends

TABLE I
Classification of Epilepsies

All types equal 0.3 per cent of population.

Type	Common EEG Abnormality	Interseizure EEG Abnormality ^a	Relative Incidence of Pure Forms ^a	Peak Age(s) of Onset ^a	Common Signs and Symptoms	Comment
I. Centrencephalic						
Grand mal	Bilaterally synchronous discharge High voltage fast activity	20% awake, 40% asleep	50%	1-15	Fifty per cent have brief aura, unconsciousness, followed by tonic-clonic seizure	Should be brought readily under drug control
Petit mal Classic absence Myoclonic Salaam Akinetic (atonic)	Three per second spike and wave; often 4 per second at beginning of seizure, 2 per second at end; easily provoked by hyperventilation	85% awake, 90% asleep	3%	5	No aura; 2 to 15 seconds of unconsciousness; may show 3 per second blinking; lightning twitches, loss of muscle tone and unconsciousness	Do not confuse minor lapses of adults, usually focal; distinguish psychomotor variant. May be quite frequent, from several to several hundred daily. Often occurs in combination with grand mal, rare in adults
II. Focal						
Jacksonian, focus around central sulcus	Focal slow activity, fast activity, or spiking	30% awake, 60% asleep	5%		Onset most common in thumb or face; motor or sensory march of symptoms	Often post-traumatic
Psychomotor (temporal lobe)	Anterior temporal lobe spike or slow wave; may be bilateral	20% awake, 80% asleep	5% alone, 15% with grand mal	20	May end with grand mal; may have independent grand mal seizures	Phenothiazines useful adjunct to therapy; surgery should be considered
Other focal	Focal spikes spreading with phase reversal to other areas	20% awake, 80% asleep				
Frontal			2.5%	3	Aura common; related to localization; onset with adverse eye movements in grand mal; and focal fits	May indicate structural lesion requiring surgery
Midtemporal				6	Facial movements at onset	Commonest focal site other than "anterior temporal." Tendency for both EEG abnormality and seizures to disappear in adulthood
Occipital			(rare)	1	Visual (unformed) aura; grand mal seizure; strabismus common	
III. Other						
Petit mal variant	Two per second wave and spike	85% awake	3%	1	Fifty per cent mentally defective; massive myoclonic jerks common; grand mal seizures	An EEG diagnostic entity with poor prognosis
Fourteen and 6 per second positive spiking (hypothalamic)	Fourteen and/or 6 per second positive spikes; usually unilateral but may appear on either side from time to time	8% show 14 and 6 awake; others show it asleep only	6%	15	Behavior disorders, especially rage attacks prominent; may have no seizures or show grand mal or visceral fits; emotional, sensory and vegetative auras	An EEG, not a clinical, diagnostic entity; atypical seizures are common

^a Data from Gibbs, F., and Gibbs, E. L. *Atlas of Electroencephalography*, vol. II. Addison-Wesley, Cambridge, Mass., 1951.

primarily on two data. A careful description of the seizure, ideally with observation, is primary. Attention should be paid to precipitating circumstances if any, periodicity (e.g., nocturnal, premenstrual, etc.), frequency, any warnings that the patient has, and particularly the very first signs of the ictus. The duration and form of termination of the seizure and subsequent state of the patient should be documented. These factors are essential in suggesting diagnosis and guiding further work-up.

In general, the major seizure phenomena should present no difficulty in differential diagnosis. Even the elaborate psychic seizures can usually be identified, partly by the patient's own conviction that they are alien events that are not an integral part of his personality. In spite of this conviction, some of the feelings are so intense and so real that the patient may doubt his sanity and interpret them as signs of disaster, which may, in fact, be his motive for seeing the physician. Occasional hysterical seizures or outright malingering present some difficulty in diagnosis until observed by an experienced clinician. Generally, these are more rarely diagnosed as epilepsy than are slightly unusual variants of focal seizures, particularly those in the temporal lobe, misdiagnosed as being hysterical.

The second datum is the electroencephalogram. The advent of the EEG 30 years ago was a major factor in bringing order into the field. It remains extremely valuable in competent hands, but, like other laboratory tools, it must be an adjunct to careful clinical evaluation. The EEG is of considerable assistance in a differential diagnosis, but, especially in the focal epilepsies, it may be difficult to obtain an abnormal record, particularly during an overt seizure of the psychic kind. For example, it is more common to find disappearance of a focal abnormality, such as a spike or localized delta focus, with apparent normalization of the record, than to find an exacerbation of the abnormality during a "psychic" seizure of temporal lobe origin. In other forms of seizure, there is usually intensification of the local abnormality at the time of the overt spell.

Two points should be emphasized. First, a single normal EEG is of no significance in an epileptic. Nearly half of all epileptics have grand mal seizures alone, and of these only about 20 per cent show waking interseizure abnormalities of the EEG. Recording during sleep increases the incidence to 80 per cent. Second, like other biological measures, the brain waves are more likely to betray abnormality under pressure, that is, during states in which cerebral integration is undergoing changes in organization. Fortunately, a number of physiological maneuvers are quite effective in this regard. Ideal, of course, is the occurrence of a seizure during recording. Every effort should be made to accomplish this naturally. (Drug activation is excluded from this urging.) Sleep recordings double the number of interseizure abnormali-

ties recorded. Only petit mal can be expected to be found regularly without sleep. Hyperventilation, by altering blood CO₂ levels, activates some abnormalities and should be carried out routinely. It nearly always activates the petit mal patient. Flickering light, with its tendency to synchronize brain rhythms, is often effective in activation. Any known seizure precipitant unique to the patient should be tried—odors, sounds, reading, tactile stimulation, etc. (One patient is activated by a xylophone rendering of "Over the Waves.")

Careful use of repeated examinations and activation should produce evidence of abnormality in about 80 per cent of all epileptic patients. There are occasions when drug activation—with pentylenetetrazol (Metrazol), for instance—is indicated. This is a special procedure that should be left to the discretion of the skilled electroencephalographer.

One word of warning. More than half of focal seizures occur in association with grand mal. Therefore, the dramatic presence of grand mal fits should not preclude the careful investigation of any focal signs or symptoms.

One extremely common error is to lump all brief lapses of consciousness into the diagnosis of petit mal and to treat them as such, often ineffectively. Petit mal is extremely rare in adults, and the occurrence of minor seizures with lapse of consciousness is much more often due to the psychomotor or other focal seizures than to true petit mal. Since the drugs of choice are rather different in the two cases, this is an extremely important distinction to make.

Centrencephalic seizures. These imply bilateral synchronous EEG abnormality at the time of the seizure and on interictal examination and clinical unconsciousness at the onset of the seizure. They include grand mal and petit mal seizures.

Grand mal seizures. They may have a brief aura and are often initiated by a cry, presumably due to forced expiration of air. (Both Gowers and Wilson object to Reynolds's classic comparison of this cry to that of a peacock in distress, but the present author has never heard a peacock in distress.) (The cry is followed by or is simultaneous with the loss of consciousness, which is followed by falling to the floor, often with physical injury, and the advent of extreme tonic spasm, the extensor muscles dominating the flexors. This is usually followed by a clonic phase, in which there is alternating flexion and extension of the body musculature, which may lead to biting of the tongue or mouth or further injury to the head. Cyanosis is often marked until the seizure terminates with deep noisy breathing and often with profuse sweating and salivation.) There may be relaxation of the sphincters, with loss of urine or feces during the seizure, and the ejaculation of semen, usually with erection, may occur in the male. (The EEG during this period is dominated by high voltage, fast activity in all leads and often terminates with an isoelec-

trict period, during which little or no spontaneous electrical activity is visible (see Figure 1). The patient may waken into a confused state described as the postictal automatism or postictal twilight state; he may become perfectly alert and oriented, though somewhat slowed down and dull, or he may lapse into apparently normal sleep for some minutes or an hour or two. On recovery, he usually complains of muscular aches (reasonably enough) and often of a severe headache. Of particular interest is a marked bulimia that may occur on recovery, especially in the twilight state, leading the patient to ingest copious volumes of food or liquid, sometimes with hazardous indiscrimination. With complete and prompt recovery, there may well be the feeling of depression and despair later mentioned by Dostoyevsky, but this is most often in reaction to concern and apprehension about the reality aspects of the seizure, social embarrassment, etc.

Petit mal seizures. The classic triad of petit mal seizures includes the *absence*, myoclonic seizures or lightning jerks (including salaam seizures), and atonic seizures. The attack is accompanied by a bilaterally synchronous EEG wave and spike formations at about three per second and is often easily brought on by hyperventilation. A characteristic attack is quite brief—10 to 30 seconds—and may pass unnoticed by the patient or by an unskilled observer. It is accompanied by total unconsciousness but of such a brief duration as to make only a transient lapse in conversation and with so little retrograde amnesia that it can easily be concealed (see Figure 2). Such seizures can be a problem if there are large numbers of them in sequence or during the course of the day. (One woman had as many as 300 recorded seizures a day.)

The myoclonic seizures are badly termed, since

myoclonus has very specific meaning in current neurological use. These attacks may or may not include unconsciousness. They are characterized by a very short jerky movement of the body, either a sudden flexion movement of the trunk muscles with raising of the arms, giving rise to the name "salaam," or, particularly in older patients, an abrupt extension movement, notably of the shoulders, arms, and hands. These patients may fall to the ground, but if they remain mentally clear, it may be difficult to distinguish these attacks from a habit spasm without EEG assistance.

Atonic seizures are literally momentary losses of muscle tone, usually with unconsciousness, causing the patient to slump to the ground but with prompt recovery.

Petit mal variants. In the EEG diagnosis of petit mal variant, the EEG record is dominated by wave and spike complexes of two per second—slower than true petit mal. These may be focal abnormalities, and there may be admixtures of slow or other abnormal activity. The clinical picture is one of grand mal or focal seizures. The onset is in infancy or childhood, and more than half of these patients have mental deficiency. The prognosis is quite poor with this diagnosis. These patients, more than any other group, are likely to die in status epilepticus. They are a small fraction of the total epileptic population and clearly should not be confused with petit mal patients.

Focal seizures. As implied by the term, these seizures have clinical or EEG evidence of a specific, usually cortical, site of origin. These are more likely to be due to identifiable pathology—a scar, vascular lesion, tumor, brain atrophy, etc.—than are the generalized seizures described above. However, the ma-

FIGURE 1. Grand mal epilepsy in drowsy male adolescent. EEG low voltage activity with random slow waves in all leads, spike seizure discharge, and run of 5 to 6 per second waves in the right frontal region. Voltage calibration: 7 mm. deflection for 50 microvolts. (From Gibbs, F. A., and Gibbs, E. L. *Atlas of Electroencephalography*, vol. II, Addison-Wesley, Cambridge, Mass., 1951.)

FIGURE 2. Petit mal epilepsy in female adolescent. Onset of petit mal seizures came at age of 8 years occurring with a frequency of 4 to 10 per day. There was no history of major convulsions, and no severe illness or injury. Family history was negative for epilepsy. EEG shows 9 to 12 per second activity in all areas, with seizure discharges of the petit mal type, in this case consisting of well formed 3 per second spike and wave formations, synchronous in all areas. Voltage calibration: 7-mm. deflection for 50 microvolts. (From Gibbs, F. A., and Gibbs, E. L. *Atlas of Electroencephalography*, vol. II. Addison-Wesley, Cambridge, Mass., 1951.)

jority of patients with focal seizures also show, either in the final stages or independently, quite characteristic grand mal seizures fitting a classic description. For this reason, work-up should be carefully directed to recognizing the localized nature of pathology that may be surgically treatable. Of particular importance in diagnosing and localizing the focal seizure are the events just preceding or initiating the attack. From these earliest symptoms, one can often make a very precise delineation of the neural structures involved.

Jacksonian seizures. These seizures, first described by Hughlings Jackson, have a focus around the central sulcus and so are introduced by contralateral focal motor or sensory phenomena. Characteristically, the thumb or corner of the mouth is first involved; the involvement then spreads by contiguity, with the characteristic march, as the seizure activity involves more and more of the adjacent cerebral cortex. If primarily motor, the manifestation is muscle twitching; if primarily sensory, the description is usually one of numbness, paresthesia, and tingling. As the march progresses over a period of several seconds, patients sometimes find that they can abort the seizure by applying vigorous sensory input to the area just above the line of march. The ancients' presumption that the occluding tourniquet effectively blocked the seizure by occluding the flow toward the brain was erroneous, but the effective sensory stimulation produced by the tourniquet was indeed useful. As long as the symptoms remain unilateral, the patient does not lose consciousness, but, as the march progresses, the motor phenomena may become bilateral, consciousness may be lost, and the patient

may show a characteristic generalized seizure. Jacksonian seizures are often post-traumatic in origin, though other pathology should be suspected. Figure 3 shows the EEG from such a case with a focus in the left parietal region.

Anterior temporal focus. An anterior temporal lobe abnormality is the commonest of the focal phenomena by EEG finding. Examples of two different patterns are shown in Figures 4 and 5. Most characteristic is the spike or a train of spikes, although slow waves may also be seen in this region. The anterior temporal lobe abnormality is accompanied most commonly by psychomotor seizures, which are particularly pertinent to the interests of psychiatrists, but it may manifest, in addition or in isolation, grand mal seizures. The clinical picture is very often characterized by lapses of consciousness, which are sometimes confused by the unwary with petit mal attacks and often begin with head turning, orienting movements of the eyes, lip smacking, swallowing, and salivation. This initial pattern may well be followed by one of the complex automatisms, stereotyped behavior, or disturbances of thought or affect, or more simply by a grand mal seizure.

Other focal seizures. Foci in the frontal, midtemporal, and occipital regions of the brain are quite rare. The EEG is usually characterized by focal spikes that may spread to involve other brain regions; for example, Figure 6 shows an occipital focus. Frontal seizures are often initiated with adverse eye movements or occasionally head movements and may involve phenomena of forced thought. Midtemporal foci are more common than the others and show an unusual propensity for the disappearance of both

the EEG abnormality and the seizures in late adolescence or adulthood. The clinical phenomena usually include grand mal seizures, and there may be focal facial movements at the onset. Occipital seizures are probably the most rare of the group, usually manifesting themselves primarily with the grand mal seizure, although there may be an initial visual aura of flashing lights, diplopia, etc. Strabismus is rather common in these cases.

Patients who show 14 and 6 per second positive

spikes are an interesting though small group. They include the "thalamic and hypothalamic" epilepsy of Gibbs. The EEG abnormality may appear in one or more leads, is usually unilateral, but is often inconstant from recording to recording (see Figure 7). Most of the subjects are preadult, and the clinical syndrome is dominated by behavior disorders, particularly destructive rage. There may or may not be motor seizures. If present, they may include grand mal, but often there are episodes of unusual visceral

FIGURE 3. Jacksonian epilepsy in sleeping male adult. EEG shows normal 14 per second sleep spindles in homologous areas. There is no asymmetry. At onset of 12 per second activity in the left parietal area, EEG increased in amplitude and became spike-like in appearance. There were no clinical manifestations. Voltage calibration: 7 mm. deflection for 50 microvolts. (From Gibbs, F. A., and Gibbs, E. L. *Atlas of Electroencephalography*, vol. II. Addison-Wesley, Cambridge, Mass., 1951.)

FIGURE 4. Anterior temporal focus epilepsy in male adult. He had a severe head injury with prolonged unconsciousness at the age of 8 years, onset of rare grand mal at the age of 10 years, onset of frequent psychomotor seizures at the age of 17 years, and aura of micropsia. Psychomotor seizure consists of groping, confused searching, and mumbling. Patient is irritable, nervous, and cries easily. Average intelligence. EEG shows low voltage 20 to 30 per second activity (F-1) in all areas with focus of 5 to 6 per second slow activity and high voltage spikes in the left anterior and midtemporal areas. Apparent phase reversal of spike discharge in all other areas is due to an active reference electrode on the left ear. Voltage calibration: 7-mm. deflection for 50 microvolts. (From Gibbs, F. A., and Gibbs, E. L. *Atlas of Electroencephalography*, vol. II. Addison-Wesley, Cambridge, Mass., 1951.)

FIGURE 5. Anterior temporal focus in male adult. He had onset of grand mal and psychomotor seizures at the age of 7 years, with no severe illness or injury. Family history was negative for epilepsy. Psychomotor attacks consist of 2- to 3-minute periods of confusion and continuous spitting. EEG shows high voltage 18 to 24 per second activity (F 2) in all leads with almost continuous spike seizure discharge in the left anterior temporal, spreading slightly to the left midtemporal area. Voltage calibration: 7-mm. deflection for 50 microvolts. (From Gibbs, F. A., and Gibbs, E. L. *Atlas of Electroencephalography*, vol. II. Addison-Wesley, Cambridge, Mass., 1951.)

FIGURE 6. Occipital focus in a male adult. There was a head injury with short period of unconsciousness at the age of 6 years. Strabismus of the left eye was first noted at the age of 7 years. Onset of rare grand mal seizures was at the age of 16 years. There were no severe childhood diseases. Family history was negative for epilepsy. EEG shows low voltage irregular 11 to 14 per second activity in all areas and spike seizure focus in the right occipital area, spreading with reversed polarity to both temporal and parietal areas. All recording was done with a noncephalic reference, showing that the recordings from the lead to the ears do not pick up the negative or the positive spike potentials and showing that they serve as quiet references. Voltage calibration: 7-mm. deflection for 50 microvolts. (From Gibbs, F. A., and Gibbs, E. L. *Atlas of Electroencephalography*, vol. II. Addison-Wesley, Cambridge, Mass., 1951.)

or autonomic disturbance that may be difficult to diagnose with certainty, although they often respond well to medication. These abnormalities may have some tendency to disappear after adolescence and young adulthood, but the behavioral disturbance in

some patients is really quite severe because of the destructive aspects.

In Gibbs's *Atlas of Electroencephalography*, the phenomena seen in this group are broken down in the following way: destructive rage episodes, 15 per cent;

FIGURE 7 Thalamic or hypothalamic epilepsy in a sleeping female adolescent. Onset of grand mal seizures was at the age of 15 years. She has rage attacks with aura of *dejà vu*, and delinquent and severe behavior problems. EEG shows 11 per second positive spikes of high amplitude, much worse on the right and showing to some extent with reversed polarity in the nasopharyngeal leads, maximal on the right. The 12 per second sleep spindles are easily distinguished from the 11 per second positive spikes. Voltage calibration: 7 mm deflection for 50 microvolts. In two cases reversal of polarity of 11 and 6 per second positive spikes has been observed in recordings from the nasopharynx, but in four cases no spike activity could be obtained with nasopharyngeal leads. (From Gibbs, F. A., and Gibbs, E. L. *Atlas of Electroencephalography*, vol. II. Addison-Wesley, Cambridge, Mass., 1951.)

localized pain, 19 per cent, plus pain as an aura to one of the other phenomena, 8 per cent; paresthesias, 16 per cent as an episodic symptom plus 3 per cent as a continuous phenomenon; episodes of syncope and dizziness, 30 per cent; grand mal or focal seizures, 67 per cent; sleep disorders, including hypersomnia, 5 per cent; emotional expressions as an episodic phenomena: weeping, 4 per cent, and laughing, 1 per cent; and vegetative symptoms, including episodic gastrointestinal hypermotility, peripheral vascular constriction, etc., and obesity, 1.5 per cent.

It is obvious that many of these symptoms would be difficult to detect as epileptic in nature, but, when characteristic, they tend to be episodic, self-limited, and unrelated to other stimuli; they often respond well to anticonvulsant medicine. It has been suggested that a number of undiagnosable episodic gastrointestinal pains of children might fall into this category, though it is likely that only a few in fact do.

Psychic seizures. In addition to an anatomical breakdown of focal seizures, one might look at focal phenomena from the point of view of the seizure content itself. Many symptoms that manifest themselves in behavioral abnormalities are related to temporal lobe dysfunction, although the primary anatomical focus may be in some other region, presumably involving the critical limbic lobe structures by spread. The lack of a one-to-one relationship between the EEG diagnosis and the clinical manifestations of the seizure reinforces the point that both must be recorded carefully and utilized in planning adequate treatment of the patient.

Psychic seizures seem to be primarily of temporal lobe origin and may either precede a generalized convulsion or, more commonly, occur without loss of consciousness. The changes may be arbitrarily divided into six categories, although any given patient may have one or more of these phenomena at various times.

Perceptual changes. The most common of these are changes in visual perception described as changes in the size of an object, as if it were receding or approaching. Everything may look very small and distant or quite large. Whenever one adolescent boy with temporal lobe seizures looked at a rose, he felt that it was approaching closer and closer, until he could see only the center of the rose, at which time he would lose consciousness and a generalized seizure would occur. The same quality may apply to auditory phenomena, so that the voices in a room become very distant or very loud and confused, as if everyone were shouting. Occasionally distortions occur, as with one patient, who described the floor and walls as becoming wavy, so that it was difficult to know where to step.

Changes in self-awareness. Striking among these are feelings of depersonalization and derealization that, as in the ambulatory schizophrenic, can be quite anxiety-producing. Such descriptions as "It seems suddenly as if all the world is on a television screen, and I'm watching a play" or "All the people on the street seem to be robots except me" or "I seem to be a disembodied spirit floating along above the crowd watching my body walk" are common. The

sensation may last for a matter of seconds or a few minutes and then abruptly disappear or be followed by some further elaboration of the seizure sequence.

Related to these feelings perhaps are the sudden feelings of intense familiarity, the phenomena of *déjà vu* or, as Strauss felicitously suggested, phenomena of *déjà vécu*—that is, the subject has the feeling that he has lived once before through exactly the same situation in which he is now, including all he sees, hears, etc. This leads to the strong feeling that he can predict exactly what is going to happen next. The reciprocal experience of *jamais vu* is also seen, in which the subject, although in a familiar situation, feels that it is entirely new to him and indeed strange. In both these situations, there is usually an awareness that the feeling is not reasonable. Such feelings are similar to those that, to some degree, are universally experienced, though more frequent and perhaps more intense.

Changes in thought. Particularly striking is the phenomenon of forced thought, in which a thought, a word, or a sentence may obtrude itself on consciousness and seem to occupy the whole center of awareness. On occasion, this may be an obscenity, but it may equally well be an apparent nonsense phrase, a tune, or a melody. Again, this state is similar to one that may occur in the normal individual on occasion but with apparently greater intensity in the epileptic. Occasionally, the thought may be a whole complex memory or sequence of memories that presents itself in a stereotyped way to the subject. It may be clearly remembered after the attack or may be only dimly remembered or forgotten, although there is a clear conviction that it has occurred before and is identical with the experience in previous attacks. This forgetfulness may occur in spite of a firm determination to remember the content, even though no further dramatic seizure phenomena follow the experience. This phenomenon, like those mentioned before, can be reproduced by direct electrical stimulation of the temporal lobe. There, too, it often has the quality of not being reported at the time or remembered later, in spite of clear instructions and willingness to do so. Disorganization of thought may be another such phenomenon, with the patient complaining that there is a brief period during which he seems to know what he wants to think about but cannot put the ideas together.

Changes in mood and affect. Paroxysmal attacks of fear ranging from anxiety to terror are frequent accompaniments of this kind of psychic seizure. These attacks are described as different from the apprehension many epileptics feel at the onset of the seizure. They are often described as isolated, free-floating anxiety far out of proportion to any external events. In a seizure in which this is a prominent feature, the whole behavior of the patient—his facial expression and perhaps muttered phrases—conveys the

feeling of intense fear. There are often expressions like, "Take it away! Take it away!" and "Don't!"

There are similar occurrences of acute feelings of despair and depression, including the feeling that life is so empty that suicide is called for. Again, these acute feelings of despair, while quite real to the patient, seldom have a specific content and usually last for a few minutes at most. Feelings of pleasure and elation seem to be somewhat more rare. Patients often report the feeling, as Dostoyevsky did, as one of serenity or cosmic understanding rather than one of pleasure. Many patients are embarrassed by such a feeling and unwilling to report it because of its somewhat mystical overtones. One wonders if it might be an element in determining that quality of religiosity commonly described in the chronic psychotic epileptic. There have also been reports of laughing as part of an attack that implicates neural structures associated with a pleasurable state.

Complex hallucinatory experiences. Although these experiences are apparently rare and may include quite complex auditory, visual, and tactile phenomena, they are probably most often auditory hallucinations with simple but well structured phenomena, such as hearing one's name called or a piece of music played. One patient always heard a poker game in the next room, with the shuffling of cards, the unmistakable click of stacked poker chips, and a mumble of voices. The patient usually has a clear insight into the hallucinatory nature of the phenomenon and feels it as alien to himself, but, unless he is unusually sophisticated, he may be quite anxious as to its reflections on his sanity. Again, such experiences are usually not reported with ease by the patient until after direct questioning and some reassurance about them.

Simple olfactory hallucinations are considered the classic aura at the onset of a fit and are often mistakenly considered a *sine qua non* for the diagnosis of a temporal lobe seizure. In fact, however, they occur in only about 5 per cent of such cases; they are more frequent in association with episodic depressive states. These are not really complex hallucinations except in association. The hallucinated odor is, almost without exception, unpleasant—usually described as burning feathers, rotting manure, like sulfur, etc. One patient described it as "the smell of death and of bodies molding in graves which pervades the environment." Obviously, this unpleasant olfactory sensation leaves ample room for secondary elaboration.

Complex stereotyped automatisms. It may be that these phenomena should not be included here, since automatisms are, in general, accompanied by loss of consciousness and amnesia and thus are more related to the twilight states to be discussed later. In contradistinction to twilight states, however, automatisms are usually short in duration, and the very

complexity of the behavior exhibited and its ties to the psychic life of the involved individual justify its presentation here.

Under this heading are included complex acts that appear to be purposeful but that are inappropriate to the situation and in general are stereotyped, that is, repeated almost identically in the same form on each occasion. A given patient may have two or three such stereotyped automatisms that seem to appear under predictable circumstances. One such patient, after brief orienting reaction and lip smacking, would, without fail, go through the motions of making up a hospital bed, complete with making square corners on the sheets and fluffing the pillow. This performance was done in pantomime and could be carried out without props, for example, on the subway or on occasion in the examining room, where he would use the examining table as the ostensible bed to be made up. Another such patient would search through whatever container was handy, throwing the contents one by one on the floor. A favorite such item was her mother's purse, but on occasion it might be the mother's dresser drawer or the doctor's medical bag. A third patient invariably undressed herself carefully, hanging her clothes in order, and then usually attempted to wander with apparent purposefulness down the street. A favorite site for this particular automatism was in the front yard of an elderly bachelor neighbor in whom she had conscious erotic interests.

On exploration, many of these acts seem to be motivated or at least to be parsimoniously interpretable in the context of the patient's interictal psychodynamics. In a few patients, a seizure could be precipitated by asking them consciously to begin carrying out their characteristic automatism under the physician's direction. In others, carrying out the act under hypnosis would give rise to a rich associative flow, further reinforcing the impression that the act had symbolic significance for the patient in the same way that a normal dream might, in spite of its stereotyped fixity of performance when elicited by a spontaneous seizure or laboratory activation of the seizure.

Twilight states. The twilight states of epilepsy are particularly important from a psychiatric point of view. They form the bridge to our understanding of the chronic disorders associated with the seizure states. Further, they are of considerable forensic importance because they provide perhaps the best possible excuse for temporary insanity under the widely applied McNaghten rule. In general, three conditions are involved: (1) the condition that may follow one or several grand mal seizures, the postictal automatism; (2) an ictal automatism, often called a psychomotor seizure and principally, although not exclusively, associated with temporal lobe pathology; (3) petit mal status, which is also an ictal rather than a postictal phenomenon.

Postictal twilight state. As defined, this state

usually follows one or several seizures and poses problems of recognition if the seizure was not observed or occurred during sleep or some similar condition. At the close of the grand mal seizure or perhaps following a period of sleep, the patient may arouse and be apparently awake but in a confused state. In this state he may mumble incoherently and fumble with his clothing or other objects. Initially, the patient is clearly disoriented to testing and, although he may be quiet during this time, periods of excitement sometimes appear, lasting for minutes to (rarely) several days. This excitement may include extreme agitation, paranoid ideation, hallucinations, and delusions that may lead to aggressive outbursts. Such a person may attack others, wander aimlessly through the community, and generally behave in a way dangerous to himself or to other people. Throughout the period, there is markedly disturbed consciousness, during which the patient seems to move around without either motor or speech impairment. There is usually complete amnesia for these periods, but occasionally dim fragments of memory of a particular event during the period may be recalled. Such states usually clear completely and often with surprising abruptness. Throughout this period of confusion, the EEG shows diffuse symmetrical slow activity, not the paroxysmal activity of the seizure state.

Ictal twilight state. In contrast to the postictal states, in which one gets the impression that there is a diffuse impairment of those central mechanisms underlying discriminative consciousness following the massive seizure discharge, are those states in which the seizure discharge itself seems to preclude organized behavior. Such ictal twilight states may begin primarily with the disturbance of consciousness and no other warning, or, more often, they may be preceded by symptoms of focal disturbance, usually of the temporal lobe, with one or more of the psychic states described earlier. Probably the single most common set of early symptoms is composed of searching movements of the head and eyes, lip smacking, masticatory movements, and swallowing, perhaps with increased salivation. During the state itself, the patient becomes disoriented and is only partially aware of his surroundings. He may wander around aimlessly, fumble with his clothing, mumble unintelligibly, or say phrases of intelligible words that are inappropriate in context. He may respond to external stimuli but does so inappropriately. One such patient fumbled opening a pack of cigarettes, one of which he put in his mouth. An observer handed him a box of matches, which he accepted but stared at uncomprehendingly, trying at various angles to read the label on the box. He did not use them for lighting the cigarette but finally laid them down on a table. During states like this one sometimes sees the complex automatisms described earlier, but vague purposelessness is more characteristic. The period may last for

5 or 10 minutes and clears either fairly abruptly or more slowly after several minutes, during which there remains some confusion and difficulty in thinking. If the state is prolonged, there may be more overt agitation, expressions of fear, anxiety, incoherent talk, and aggressive acts, particularly if attempts are made to restrain the patient.

Of rather more interest than this grossly disturbed behavior are those patients who present apparently purposeful and well coordinated behavior with no recall or only dim memories of the period, which may last hours to days. Such patients have come to suddenly with their last memory being that of approaching a platform to give a speech and every subsequent report confirming that it was given without a blemish, with no evidence of any abnormality on the part of the speaker, although he was apparently in a seizure state throughout the time. Even piano concerts have been completed under similar circumstances.

What may be more interesting than what would seem to be the carrying out of well programmed though sophisticated sequences of activities are those subjects who find that they have digressed from a planned course of action, perhaps negotiated a difficult transportation system with business transactions and landed in a city some miles distant, in a hotel room with plane tickets in their pocket and no recollection of the intervening events. These fugue states may last from several minutes to a few days and obviously can be a source of concern to the patient and those close to him. Although it seems possible that some accident may be caused or a crime committed during this period, such events must be relatively rare and more a source of fantasy guilt for the patient than a major social hazard. One patient had episodic kleptomania, apparently on the basis of a temporal lobe focus, which was controlled with medication but recurred on occasions when medication was interfered with.

These fuguelike states are potentially very difficult to differentiate from hysterical episodes or from out and out malingering. The EEG may be of little help because a striking electroclinical correlate of these seizures is often the forced normalization of the EEG, with disappearance of whatever abnormality may be evident interictally or, perhaps more commonly, an unchanged pattern of the EEG from that seen at ordinary times. On rare occasions there may be some exacerbation of local pathology, but that is the exception rather than the rule. Depth electrography, when otherwise indicated, may help clarify the diagnosis of these cases.

Petit mal status. The twilight states associated with petit mal status are relatively uncommon but have been emphasized by Landolt. The EEG in these cases is characterized by continuous or nearly continuous bilaterally synchronous spike and wave patterns, and the clinical picture is apparently dominated by confusion but frequently with fairly complex con-

fused behavior, as described for the postictal twilight state. An attenuated form of this same phenomenon may appear in patients who complain of mental dullness, which may last for several days, characterized by difficulty in concentration and general slowing of the thought processes without the confusional picture just described. In these patients, too, the EEG may reveal almost continuous runs of spike and wave activity dominating the electrocortical rhythms. These protracted periods of mental slowing may terminate abruptly or be terminated with adequate treatment. They clearly represent a form of petit mal status that somehow is not so intense as to dominate consciousness and orientation.

Mechanism

(Our knowledge of the chemical and structural pathology of the epileptic focus has grown rapidly in recent years, but a comprehensive discussion relating these factors to the psychiatric aspects of epilepsy is, unfortunately, still impossible.) The mechanism by which certain scars, tumors, ischemia, and inflammations produce a hypersynchronous neuronal discharge is far from obvious, as are the reasons for the varying seizure thresholds throughout the brain. The latter phenomenon complicates the problems of the neurologist because it is compounded by the essential complexity of the interconnections of various areas of the brain. Indeed, these features underlie the occasional finding after a temporal lobectomy that no anatomical lesion exists in the extirpated tissue. The EEG may have limited value in localization, as illustrated by the cases of Falconer et al. in which the EEG showed an anterior temporal focus but x-rays revealed calcified lesions near the parietal-temporal junction, and by cases in which histological lesions were contralateral to temporal EEG abnormalities.

Temporal lobe pathology has received the most attention in the last decade because epilepsy in this area is most recalcitrant to any therapy and most likely to be submitted for surgical treatment. Also, this area, with its underlying rhinencephalic structures, has been implicated in the fascinating functions of memory and emotions. Falconer et al. found that the most frequent lesion associated with unilateral temporal malfunction in epileptic patients undergoing temporal lobectomy is medial temporal sclerosis (Ammon's horn sclerosis or incisural sclerosis), which has an incidence of 47 per cent (versus 24 per cent for small tumors, 13 per cent for scars or infarcts, and 22 per cent with no obvious pathology). These figures agree with those of other investigators, most of whom arrive at the same conclusion—that the ability to find and extirpate an identifiable lesion increases the chances for cure or control of the seizures and concomitant psychiatric disorders. Ammon's horn sclerosis seems to be asso-

ciated with an early age of onset (before the age of 9 years in most cases) and with favorable prognosis.

Further correlations, the site of lesions with psychopathology, for instance, are incomplete and inconclusive but certainly demand investigation. One pertinent relation between epilepsy and pathology was found by Morrell, who has shown that mirror foci with concomitant histological changes can be produced by experimental epileptogenic foci. This observation argues strongly for early diagnosis and vigorous therapy, for little is known about the potential damage to other brain areas that can ensue from an active focus.

Studies of the biochemical changes in epileptic foci recently invaded the literature on epilepsy, taking their cue from work on schizophrenia and stimulated by the finding that pyridoxine deficiency can both lower the levels of brain γ -aminobutyric acid and cause convulsions in humans. This finding led to the examination of the changes in other cerebral amino acids and their derivatives with the hope of finding more specific and potent therapeutic agents. So far, the results are interesting but contribute more questions than answers. Various congenital metabolic disorders, such as phenylketonuria, produce convulsions and probably provide the best tactical approach to the biochemistry of epilepsy—the cryptogenic variety, at least.

Of particular importance is the recent study by Hagberg et al. of amino acid excretion in 43 children with cryptogenic epilepsy and normal plasma pyridoxal phosphate levels. Over 60 per cent of these children had abnormal tryptophan-loading tests (its degradation requires pyridoxal phosphate). Giving 160 mg. of pyridoxine by mouth improved about 40 per cent of those with abnormal tryptophan metabolism, some dramatically. This suggests that a state of pyridoxine dependency may exist and that tryptophan loading should be routinely tested in epileptics.

Incidence and Epidemiology

As is customary in the United States, it is very difficult to arrive at reasonable statistical estimates of the incidence, prevalence, or distribution of a non-reportable disease, which, of course, epilepsy is. In general, perhaps half of the cases in this country are preventable in the sense that they are the sequelae of trauma, infections, birth injury, etc., with clear damage to the brain, and seizures appear as a secondary symptom of the underlying brain damage—perhaps the least dramatic of the symptoms when cerebral palsy or mental deficiency dominates the picture. These secondary cases are clearly increased when there is poor prenatal and perinatal care and in regions that pay the usual price of poverty and overcrowding in malnutrition, neglect, and violence.

From a world health point of view, epilepsy is a very common and disabling condition, particularly in regions where there is a high incidence of low

virulence central nervous system infections causing secondary cases and where traumas, particularly the subdural hematomas of infancy and early childhood, are neglected. However, in our relatively fortunate country, the incidence is about 0.3 to 0.4 per cent or roughly one tenth the incidence of mental deficiency and perhaps one half the incidence of schizophrenia.

To assess this problem, Kurland utilized the Mayo Clinic statistics on the population of Rochester, Minnesota, a small Midwestern town in a relatively rural setting and probably of above average economic status and certainly of above average access to medical facilities. Extensive records have been kept over a period of time by the Mayo Clinic, and it was possible from these for Kurland to make some reasonable estimates concerning statistical distribution of the epilepsies. He noted that the average annual incidence rate is 29.8 per 100,000 population per year, the rate being slightly higher for males than for females for all types of seizures combined. The extrapolation suggests that the numbers of new cases in the United States each year by his categories are approximately as follows.

Grand mal, primary.....	15,000
Grand mal, secondary.....	14,000
Petit mal.....	6,000
Psychomotor.....	5,000
Focal motor and sensory.....	11,000
Miscellaneous or unclassified.....	2,000

Kurland rightly noted that these figures are based on a relatively small population and must be interpreted with caution, but there are probably no better ones to go by at the moment. It is interesting to note the age distribution for the initial episode. The rate is highest for ages 0 to 4 years, reaches a low level after adolescence, and peaks again after 70 as the result of late cerebral disease.

As to prevalence, Kurland noted that the age-adjusted rate (adjusted to the United States population for 1950) for all types is 376 per 100,000 population. Applying this figure to the total United States population, he estimated that about 640,000 individuals are subject to recurrent convulsive disorders. The numbers in each type are approximately as follows:

Grand mal, primary.....	292,000
Grand mal, secondary.....	116,000
Petit mal.....	39,000
Psychomotor.....	105,000
Focal motor and sensory.....	73,000
Miscellaneous and unclassified.....	14,000

It is perhaps worth noting that approximately 15 per cent of these cases are psychomotor epileptics. Other authors have estimated that approximately 20 per cent of the epileptic population have psychomotor or temporal lobe seizures.

Psychiatric Aspects)

It is difficult to say what psychiatric difficulties characterize the epileptic population and what psychiatric difficulties are caused by the presence of seizures. Most psychiatric difficulties, except for the major psychoses, are quite widespread throughout the population and can be expected to involve the epileptic population by chance. It is thus necessary to indicate a greatly increased incidence of abnormality, suggesting a special proneness in the seizure patient, or else to delineate a unique syndrome of a personality disorder that can be identified with and perhaps limited to the epileptic group, if one wants to incorporate the epileptic state into a total diagnosis, as would seem to be reasonable. Is there then anything systematic we can describe about the epileptic who is not having a seizure and is not in a postictal state, which is, after all, most of the time?

Personality of the epileptic)

Social problems. Kurland's figures suggest that some 60 per cent of all epileptics and nearly two thirds of the centrencephalic or idiopathic group have the onset of their seizures in the 1st decade of life, which means that these individuals have grown up with a rather dramatic handicap. In spite of some recent publicity, still a great miasma of social taboos and misapprehensions about the epileptic seizure beclouds the individual's adjustment. Many schools will not allow the epileptic in class, and a fair number of classroom teachers are both frightened of the child who has a seizure and willing to ridicule him. Parents may be ashamed and apprehensive, guilty and overprotective, or they may feel frightened and impotent with their child's seizures.

In later life, employers and employees discriminate against hiring the epileptic, as much because of the frightening experience of witnessing a seizure as because of real concerns about job injuries. The ever present possibility of a major seizure in public, with the attendant helplessness and the inevitable social embarrassment, hang heavily over the epileptic, even though he may have rare seizures. If he understands his condition, it is clear to him that he has a problem with which he must live for the rest of his life, that it is incurable, and that he may have to take medication and guard against precipitating influences as long as he lives. Under these conditions, it is not surprising that he has difficulty in establishing that sense of personal security and clear ego identity hoped for as a foundation for mental health in later life.

It is in this area that the understanding physician can do a great deal for his patient. If he is willing to add to his vigorous attempts at medication control of seizures, he can give some personal counsel, intervene in parental misapprehensions, and do occasional battle with the school system, the scout troop, and other social establishments. In the face of the problems to be handled, middle class patients who

have been under reasonably competent medical care do a quite commendable job in making a productive, stable life adjustment. This is not true, however, in that sizable part of our population currently described as "disadvantaged." For them the problems of the epileptic are magnified because they fall just below the marginal utility of their group. This leads to rapid ostracism, neglect, and a downward spiral of social alienation and physiological abuse.

Physiological problems. A second class of problems besetting the epileptic are a little harder to evaluate in terms of long range effect. These are the problems attendant on the presence of a recurrent abnormality of brain function that occurs unpredictably and with much greater frequency (as revealed by the EEG) than is manifest by the overt seizure. In the case of petit mal epilepsy, these effects are very clearly demonstrated in clinical experience. Children who have few overt seizures but many bursts of EEG abnormality are found to have difficulty in school and in making peer adjustments. This might be expected from a child whose brain is turned off 20 to 30 per cent of the time without his being aware of it. The fact that such a child can survive a school situation at all and make any sense of a teacher's discourse or of reading material is rather impressive. In fact, however, many children cannot do this, and they present themselves as learning problems or behavior problems as they react against the confusing situation in which they find themselves. Adequate medication often dramatically and gratifyingly corrects this situation.

It is less obvious but seems likely that other paroxysmal discharges, such as the grand mal or the temporal lobe discharge, may have similar cumulative effects on the individual's ability to integrate life experience. The seizure discharges in the temporal lobe—shown in depth electrography to be often widespread and profound in subcortical, particularly rhinencephalic structures, although not evident on scalp recordings or as a clinical seizure—must be disruptive of normal functioning of these important integrating systems. Far too little is known of the role of these deep structures in total behavior, but it seems apparent from experimental work that they are quite important in the integration and expression of emotion and in learning and memory. If they are regularly disrupted or deranged by seizure activity, it seems unlikely that the patient is able to utilize optimal cerebral resources for the difficult job of making an adequate life adjustment.

The problem of paroxysmal cerebral dysrhythmia, the complications of poor medical control—leading to frequent falling and self-injury, usually involving the head, with possible attendant secondary brain damage—and the potential problems of chronic drug intake add up to a heavy set of physiological hazards facing the epileptic individual. These problems can be reduced by good medical management, particularly

with scrupulous attention to medication schedules that leave the patient seizure-free, with few or no interseizure paroxysmal discharges and without beclouding by drugs. This state can be achieved in many patients with petit or grand mal epilepsy. It is much more difficult in the patient with temporal lobe seizures.

Adjustment to seizures. Having epilepsy and having seizures become integral parts of the epileptic's life, and it is not surprising to find them intricately interwoven into his life adjustment, as are many disabilities. In particular, there is the problem of the patient who utilizes his seizures for secondary gain, either to attract attention or to avoid uncomfortable situations. Some epileptics learn to do this consciously if their seizures can be precipitated by hyperventilation or similar physiological maneuver. In others, one has the feeling that the link is not deliberate but becomes a kind of conditioned reflex response to certain kinds of psychological stress. In a small group of patients, particularly children, seizures are self-precipitated, apparently for some physiological reward. Dramatic among these are those subjects whose seizures can be precipitated by flickering light; they will stare at the sun and wave their hands in front of their eyes to produce a flicker effect. Some other children, particularly those with petit mal, can achieve the same thing by hyperventilation and will do so whenever they are bored or in an unpleasant situation. It is not at all clear what the gratification is or whether it is different from what seems to be man's diffuse impulse to enjoy consciousness-clouding chemicals or activities. It seems likely that the mechanism is related to the dramatic self-stimulation of the brain shown by animals with electrodes in appropriate regions of the neuraxis. Careful study of this phenomenon in man may elucidate some of the paradoxes of self-stimulation in animals.

Quite independent of self-induced seizures, emotional factors play an important role in the production of some individuals' seizures and perhaps in the over-all frequency of seizures. It has been suggested that stressful interview is a much more effective activator of EEG abnormalities in the temporal lobe epileptic than are the traditional methods of hyperventilation, flicker, or even drug induction. In the day-to-day follow-up of the patient, a fair number of seizures seem to be related to emotional stress rather than to more obvious physical-chemical phenomena, such as fatigue, fever, alcohol, hypoglycemia, and other known provocative states. One of the common denominators of those psychological situations that provoke seizures is the active control of a strong emotion or motivation, anger particularly. In the experimental animal, trained inhibition of a response, particularly under strong motivation, is often accompanied by widespread slow waves through the EEG, suggesting a hypersynchrony of

the underlying neural aggregates. This physiological state provides a common ground for the development of seizure activity and may be the intervening mechanism in such patients.

At quite another level, there are patients who have real seizures but who, on occasion, malingering seizures for their own purposes. These, of course, become very hard to identify outside of a hospital setting. Indeed, a patient with somewhat bizarre temporal lobe seizures and a hysterical personality can push one's diagnostic and therapeutic skills to near desperation.

Aura. The very earliest symptoms in a seizure, particularly the aura, have an important localizing value in cases of focal epilepsy. The aura is perhaps of equal importance to the epileptic himself, for it warns him of the onset of a seizure and allows him a little time to find a safe place to lie down, park his car, etc. The aura is often present, even in the primary grand mal epileptic (though not in the petit mal), and has various qualities. The acute phenomenon is frequently described as diffusely visceral, "the feeling of butterflies in the stomach," "a feeling of fullness in the head," "a general feeling of apprehension, as if something were about to happen," etc. This feeling may last for only a few seconds or several minutes before the overt seizure.

Equally frequent, though sometimes more evident to astute observers than to the patient himself, is a period of several hours or days of increasing irritability, restlessness, and mild depressive symptoms that precede a major seizure. These symptoms usually disappear abruptly after the seizure itself.

In patients who are under good medical control so that overt seizures are infrequent or absent, two phenomena may occur. One, there may be paroxysmal occurrences of the characteristic aura that pass abruptly, as if a paroxysmal discharge had occurred but had not spread into a generalized full blown seizure. Indeed, on the electroencephalographic examining table, this seems to be the case. The second phenomenon is of more interest. Some patients under good control develop protracted states of irritability, nervousness, or depression, as outlined above, with gradually mounting tension. Many of them recognize the phenomenon and will deliberately skip medication for a day or two in order to precipitate a seizure and clear the air. On careful questioning in a cooperative clinic, a large percentage of otherwise well controlled patients will confess to this, although they are reluctant to volunteer it, having been badgered by their physician for some years to maintain a strict medication intake.

A phenomenon that is of particular interest has come to be called "continuous aura." The term, first used by Masland and Scott, seems to imply a low level constant dysrhythmia that is not, in general, demonstrable on the EEG, unlike the case of the paroxysmal, more discrete auras. It reflects some unique organization that is altered by the major seizure, and

it raises interesting questions about the reciprocal relationship between the seizure and the patient's mental state. Strauss noted that a number of these individuals with protracted preictal auras or a continuous aura phenomenon turn to alcohol in an attempt to relieve their symptoms, and they are a definite subset of periodic drinkers.

The "epileptic personality." Does there exist a characteristic "epileptic personality," as insisted upon by Kraepelin and promoted periodically since by other writers? Those who insist on a set of common personality traits identify the following: slowness of reactions, perseveration on a subject with circumstantiality (sometimes called adhesiveness), rigid emotional attitudes, unresponsiveness to external factors, self-centeredness, hypochondriasis, and fixed opinions, particularly concerning religious issues. Most authors, however, agree that, in noninstitutionalized epileptics as a group, these are not characteristic features and that personality types and abnormalities show the general broad range noted in the rest of the population. It may well be that many of the traits described are not issues of personality but reflect the underlying cerebral dysfunction, which may persist in the absence of overt seizures. From time to time, one sees patients who fit the description outlined above who are remarkably improved by adjustments of medication or by surgical intervention, suggesting that they are not fixed traits but symptoms of impaired brain function.

The same question had been raised in a different way about patients with temporal lobe epilepsy. Gibbs was perhaps the first to emphasize what he felt was the very high incidence of psychiatric abnormality in patients with temporal lobe epilepsy. Although the psychiatric symptomatology covered the entire spectrum of possibilities, a similar point has been made about patients with temporal lobe disease in general, independent of the presence of epilepsy, by Mulder and Daly, among others. Many clinicians have repeated the feeling that patients with temporal lobe disease are an unusually disturbed sample of the population. Ervin et al. emphasized that in those patients with temporal lobe EEG abnormalities, with or without the presence of seizures, there were common behavioral difficulties. These were particularly the mobility of mood, the sudden alterations in states of consciousness, the frequency of hallucinatory experiences, and, in particular, a wide assortment of episodic symptoms, often short-lived, that were not ordinarily thought of as ictal. Another striking difficulty was in the area of impulse control, which seemed to be particularly poor in these patients. There were also disturbances of thought and peculiarities of affect.

It was emphasized at the time that these difficulties were like those that have come to be associated with the schizophrenic process. But there is no gain in lumping these cases in the wastebasket of schizo-

phrenia, which is already overcrowded. However, of those cases showing symptoms often diagnosed as schizophrenic, there is a subgroup of patients who can be characterized as having temporal lobe EEG abnormalities and often temporal lobe seizures. They should be isolated and subjected to further etiological and therapeutic investigation. Informal estimates have been made that as many as 10 per cent of the acute schizophrenic episodes in a receiving hospital may represent this group of patients.

A strong exception to this position has been taken by Dr. Janice Stevens, an able and experienced contributor to studies in epilepsy. She has cited evidence that temporal lobe epileptics do not differ from other epileptics in the incidence or severity of psychiatric disorders. In deference to her considered criticisms of the evidence accumulated to date, this must remain a debated issue until a common set of descriptive terms can be applied quantitatively to geographically remote populations for comparison.

Acute psychotic states related to epilepsy. Kleist first described a group of episodic psychoses he felt were related to but not identical with epilepsy. Since that time, a number of authors have described short-lived schizophrenia-like psychoses in patients with temporal lobe seizures. Hill, particularly, has described EEG changes in certain episodes of "catatonic schizophrenia" that often terminate with a grand mal seizure. Ervin et al. emphasized the same phenomena and pointed out again the suggested reciprocal relationship between the presence of overt seizures and the presence of overt psychotic behavior. This phenomenon has also been reported as a side effect of the administration of phenacemide (Phenurone), which is one of the more effective, though more toxic, anticonvulsants for temporal lobe seizures. These episodic psychoses look in many ways like acute schizophrenic attacks and would ordinarily be categorized most commonly as catatonic, paranoid, or acute undifferentiated schizophrenia.

An investigation of such acute psychotic disorders was reported by Dongier as a summary of a collaborative study in a number of European centers. A total of 536 psychotic episodes occurring in 516 epileptics between clinical seizures were evaluated with a set of standard forms that detailed the clinical symptoms of the psychotic episode, the EEG manifestations during the episode, a psychiatric classification of the episodic behavior, and an electroclinical classification of the patient's epilepsy. Even in such a collaborative study, obvious difficulties were present in finding a common terminology for similar events. The general effect of these difficulties, however, was to weaken any distinctions between groups. The conclusions they reached were of particular interest insofar as they reinforced the studies from a single center.

For their work, the researchers differentiated generalized centrencephalic epilepsy, focal epilepsy

(frontal, central, parietal, and occipital), and psychomotor epilepsy or so-called temporal lobe epilepsy. For much of the analysis, the psychomotor and focal epilepsies were taken as a group, to be compared against the centrencephalic cases.

A first point from their study is that, of 516 epileptics who showed interseizure psychotic episodes, 44 per cent of them turned out to be cases of psychomotor epilepsy, and only 6 per cent were cases of other focal epilepsies. Since the general incidence of psychomotor epilepsy in a total epileptic population is 15 to 20 per cent, this suggests a unique propensity of the temporal lobe cases for severe psychiatric disturbance. Looked at the other way, from the personal cases of Dongier, psychotic episodes were found in 30 per cent of generalized and 63 per cent of psychomotor epileptics in a series of 83 epileptics.

Another finding from this series was that, during the psychotic episode, some 65 per cent of the temporal epileptics showed disturbed affective reactions, as compared to 46 per cent of the centrencephalic cases, and 45 per cent of the temporal lobe cases showed depression, as compared to 24 per cent of the centrencephalics. This heightened incidence of affective disorder is consistent with the findings suggested about the interseizure personality in the temporal lobe group.

The general findings about psychotic episodes may be summarized in the following way.

Centrencephalic epileptics. Dongier stated, "These patients frequently show psychotic episodes which are relatively brief in duration (several hours). The episodes are never chronic nor do the patients become permanently mentally disturbed or demented. The episodes often begin but rarely end with the seizure." Two thirds of these episodes were of a confusional type. The EEGs were nearly always modified during the episode, usually in the direction of a diffuse slow dysrhythmia or with frequent spike and wave discharges that sometimes developed into a classical EEG picture of petit mal status. It was extremely rare to see unmodified tracings or tracings modified in the direction of normality. It seems reasonable to agree with Dongier's conclusion that these cases represent prolonged postictal states; indeed they would fall into the conditions described as postictal twilight states and would not be described as psychotic episodes.

Psychomotor epileptics. This group had psychotic episodes lasting days or weeks. They were rarely preceded by a tonic-clonic seizure but often ended in one. Dongier reported that they are distinguished from the other group in the following ways: (1) "Confusion is not always present during these episodes. They were usually characterized by disturbances of affect such as mood swings (with anxiety and particularly depression but with normal consciousness)." Paranoid ideation was also marked in these cases. (2) "There is never a continuous spike and wave

discharge during these episodes and only rarely is there slow wave dysrhythmia. On the contrary, we often observe either unmodified background rhythms or desynchronized tracings with disappearance of normal rhythms as well as disappearance of pathological activity (the 'forced normalization' mentioned before)" or (3) "occasionally a reinforcement of focal epileptic discharge in the temporal region without modification of the background rhythms."

In summary, temporal lobe epileptics particularly may show acute psychotic episodes with prominent schizophrenia-like features and little or no EEG abnormality to suggest a relationship to epilepsy. These may last for days or weeks and end abruptly. In addition, it seems likely that there is a group of patients, not manifesting clinical temporal lobe epilepsy, who on examination do show temporal lobe EEG abnormalities and who manifest acute or subacute psychotic episodes, which are often misdiagnosed as schizophrenic. These patients may suffer from the same basic pathophysiology as the known epileptics, and vigorous medical or surgical treatment may improve their prognosis considerably. One might clinically classify in this group a set of patients, in general young, who do not show florid psychotic symptomatology but who manifest primarily episodic behavior disorders, lack of impulse control, and affective lability. They are frequently difficult management problems on the ward and pose problems in diagnosis, frequently being thought of as borderline cases with hysterical character disorders or the like.

Chronic psychotic states and epileptic deterioration. Like the problem of the epileptic personality, a traditional picture of the epileptic psychotic or the deteriorated epileptic has existed. One sees in state hospitals a number of chronic epileptic patients in whom the combination of recurrent seizure, social neglect, recurrent head injury, and perhaps overmedication have led to a sad state of deterioration, but it seems unlikely that there is any unique psychotic end point for the epileptic. Even many of the apparently deteriorated cases can be markedly improved by good medical attention. Some epileptic patients face the statistical coincidence of a schizophrenic psychosis in addition to their epilepsy. The issue has been critically reviewed by Bartlett, who cited most of the pertinent statistical studies and who concluded that chronic schizophrenic psychoses do not occur more frequently in epileptics than in the general population. However, in several studies, those psychoses that do occur in the epileptic population occur primarily in those patients with temporal lobe epilepsy.

This observation adds fuel to the extensive study by Slater et al. of a group of schizophrenia-like psychoses occurring late in the course of temporal lobe epilepsy. They studied a group of patients with temporal lobe seizures of varying etiologies and oc-

currence at various times in life. The patients were admitted to the hospital in a psychotic state, with secondary symptomatology of delusions and hallucinations, psychotic depressions, and the like. Slater et al. concluded that these states tended to occur in patients an average of 14 years after the onset of temporal lobe pathology and independent of the severity of the seizures, the etiology of the epilepsy, the amount of medication taken, or the adequacy of medical control. They further differentiated this group genetically from their schizophrenic patients and outlined a clinical syndrome that they felt differed from the schizophrenic group, primarily in showing more signs of organicity. These patients tended to have a very poor prognosis, and the authors concluded that their psychotic syndrome was uniquely related to the pathological state of the temporal lobe.

This careful study should be extended to a larger group of patients, because it raises serious concern as to whether the persistence of temporal lobe (presumably subcortical) electrical abnormality poses a long term hazard of serious disability to the patient. Should this be the case—and in the light of the poor ability to achieve medical control of these seizures—the indications for relatively early surgical intervention in these cases might be broadened with the advances in surgical technique and safety.

Genetics and Marriage

From the Middle Ages in Scotland, when any man with epilepsy was castrated and any epileptic woman was buried alive with her children, to our enlightened age in the United States, in which several states have laws forbidding the marriage of epileptics, superstition and ignorance have caused the epileptic patient unjustified harassment in his role as procreator. The new science of behavioral genetics has only begun to clarify the pertinent issues, and it is up to the clinician to bridge the chasm between the statistics and the individual patient.

The twin pair data of Lennox and other workers indicate a strong inheritable predilection for epilepsy. When they divide the epilepsies into cryptogenic and symptomatic, they find among the cryptogenic about 85 per cent concordance for epilepsy in the monozygotic twins (versus 5 per cent for the dizygotic twins), and among monozygotic twins with symptomatic epilepsy they find about 14 per cent concordance (versus 0 per cent for dizygotic twins). This shows that manifestation of epilepsy is not inevitable, even in identical twins, but sensitivity does seem to be inherited, even to symptomatic epilepsy. Studies on post-traumatic epilepsy among Korean War veterans supports this view by showing the incidence of epilepsy among close relatives of those who developed epilepsy following head injuries was 7 per cent, as opposed to 1 per cent of the close relatives of soldiers who did not develop epilepsy after similar trauma. However, other

studies have found fewer differences, leaving the issue debatable.

Sensitivity to epilepsy varies among the general population. For example, when one looks at the severity of the EEG driving by photic stimulation, one obtains a bell-shaped distribution, with no abnormality at one extreme and convulsions at the other. The same phenomenon may also be observed for other means of epileptic activation. Similarly, Gibbs and others have discovered that about 10 per cent of the normal population have EEG abnormalities that do not produce any known clinical symptoms. Lennox has advanced the theory that the genotype determines the cerebral dysrhythmia rather than the convulsions, but because of the technical problems involved, little work has been done on the inheritance of the EEG pattern.

The variety of the epilepsies and their causes contributes difficulties to their genetic study because they do not form a genetic entity and each patient must be considered separately. Lennox has found the incidence of epilepsy in relatives of epileptics (2.5 per cent) is five times that in the general population (0.5 per cent). One of the few genetic analyses of a specific type of epilepsy was done by the Metrakoses on centrencephalic patients. They found a significantly higher (13 per cent) than normal (2.5 per cent) incidence of convulsions in the parents and siblings of centrencephalic epileptics. The most striking correlation was the 36.8 per cent incidence of cerebral dysrhythmia among the siblings of the centrencephalic epileptics. They concluded that the centrencephalic type of EEG is the expression of an autosomal dominant gene with highest penetration from the ages of 4 to 16. Another study showed that focal temporal EEG abnormalities behaved as the phenotype of an autosomal dominant gene in 10 families. These studies mark a change in emphasis in the genetics of epilepsy from the overt seizure to the underlying and more fundamental specific electrical dysrhythmia, a refinement that may prove very fruitful.

Most patients rightfully have little interest in these general statistics and are more concerned with their own particular chances. Clinicians can best help them by determining the familial characteristics of each patient's specific disease from carefully taken pedigrees and, if possible, from EEG studies of close relatives.

Marriage laws concerning epileptics are antiquated and usually disregarded. In counseling couples, the most important function of the clinician is to inform and reassure both the patient and his future partner, the latter having particular importance for the happiness of the marriage. When the couple asks about having children, the first consideration is whether the patient's physical and mental condition allows him to be a good parent; only then can the discussion be directed toward the genetic possi-

bilities. If only one future parent is afflicted with epilepsy and if head injury has been eliminated as the precipitating factor, the current estimate is that each of their children has a probability of between 0.025 and 0.05 of developing overt convulsions—a very slight risk. Evidence shows that this probability is increased if the other future parent has subclinical cerebral dysrhythmia or if both have epilepsy, but accurate figures are unavailable. Again, it is necessary to emphasize that meticulous study of pedigrees is of more validity than applying figures from the general population. It appears that the risk of transmitting epilepsy alone is generally too minute to warrant advising strictly against progeny, especially now, when so many convulsions can be completely controlled or cured by drugs or surgery and the outlook is auspicious for further advances.

In closing, one can add little to Strauss' view on eugenics and epilepsy:

Having children is always a joy and a risk. Whether an epileptic will want to take the additional risk of a possible transmissible disorder is not a matter which can be decided by any statistics. A decision can be made only by the prospective parents after they have been acquainted with the available knowledge and have been told frankly that any definite prediction as to the condition of their prospective children cannot be made ... even if a child should be sick from a convulsive disorder, probably it will be possible to make this child a happy human being.

(Treatment

Medication. The heart of the treatment plan for the epileptic is the adequate use of medication. Most seizures can be controlled with medication, but the vigorous and imaginative application sometimes required is often neglected. The keys to effective medical control lie primarily in two groups of drugs. For petit mal seizures, trimethadione (Tridione) and paramethadione (Paralidone) are the drugs of choice. On occasion in petit mal status or in some of the twilight states presented by them, the use of an amphetamine, particularly benzedrine, is extremely effective. These drugs have little or no usefulness in seizures other than true petit mal. All other seizures are best initially treated with diphenylhydantoin (Dilantin) or Dilantin in combination with phenobarbital.

Should this approach not be effective or be precluded by toxic or allergic reactions, a broad spectrum of other drugs may be used. These are added to from year to year, and the choice of them seems to depend somewhat on the individual physician's preference and on the unique peculiarities of the particular patient. At the present time, particularly useful drugs are methylphenylethylhydantoin (Mephentoin), primidone (Mysoline), chlordiazepoxide (Librium), and methsuximide (Celontin).

In working out an acceptable drug regime for a patient, one should systematically push the dose of an initial drug to its limit of effectiveness. If it proves

unsatisfactory, one should reduce the dosage somewhat, systematically adding another drug. Abrupt withdrawal of any of these compounds should be avoided, as there is danger of throwing the patient into protracted seizures. The goal of drug juggling should be *complete* control of seizures. Control at the level of one seizure every 6 weeks may be quite satisfactory to the physician, who has seen the patient have three and four a week, but it is not good enough for adequate rehabilitation of the epileptic. One seizure every 6 weeks may be just enough to preclude a normal social life and gainful employment. It sometimes requires a great deal of time, careful record keeping on the part of the patient, and patience and faith on the part of the physician to work out a schedule and combination of drugs that effectively controls the seizures and does not produce untoward symptoms. Along the way it may be necessary to utilize some mild stimulant, such as an amphetamine, to counteract the drowsiness produced by adequate medication, although this is not usually a problem.

All these drugs are potentially toxic and particularly affect the hematopoietic system, so that any patient on these drugs should be observed regularly and have hematological examinations. All the drugs have a finite frequency of allergic response, and this, too, should be watched, or they may in themselves produce toxic psychoses, which can be confused with phenomena related to the epilepsy. Should such a question arise, adequate determination of blood levels and changing of the drug are in order. Particular attention might be drawn to Phenurone, which is often quite effective in temporal lobe seizures notoriously resistant to other forms of drug medication. It is, however, an extremely toxic drug with liver complications and with a relatively high incidence of psychotic disorders occurring even when there is good seizure control. Phenurone should be used quite carefully and, if it is necessary to utilize it, should probably be initiated under hospital surveillance, with frequent checkups thereafter.

Adjuncts to therapy sometimes include shifting of the acid-base balance, particularly in the petit mal patients. Acetazolamide (Diamox) or a similar carbonic anhydrase inhibitor may be useful. The details of drug dosage, side effects, and monitoring should be looked up in some current handbook of therapy before embarking on a vigorous medication regime.

Attention should also be paid to maintaining physiological homeostasis for the patient. Seizure threshold may be lowered by fever, fatigue, salt and water retention, etc. Should these conditions occur because of intercurrent illness, it may be desirable to increase medication. The patient should be a party to an understanding of drug use and planning and can often judge for himself when a temporary increase in medication is called for. If he has the feeling that

he has the respect of his physician, these changes, which he will carry out anyway, will at least be communicated to the physician to prevent embarrassing dilemmas. At the same time, although he should be aware of these problems, which may increase his propensity to seizures, it should not be necessary to frighten him into immobility and from some attempt to lead a reasonably normal life. In this regard, alcohol poses a particularly tricky problem, since in excess it may well increase the seizure susceptibility, especially during the withdrawal period. Some experience with the individual patient should lead to a suitable evaluation of this issue.

Psychotherapy. Since the epileptic patient has a condition that may well persist for life and around which his future must be organized, it is well for him to have a reasonable psychotherapeutic relationship with his physician. This need not imply regular or insight-directed psychotherapy, but it should imply the kind of relationship that allows time for the patient to talk over his concern about the social problems involved in getting jobs and in wooing a mate, inheritance of his condition by his children, etc. The physician may well have to be prepared to intervene in some situations, particularly in those school systems that are so primitive as to preclude epileptic children of normal intelligence from classroom activities. Problems of driver's licenses, hazardous work, legal responsibility, etc., all need the thoughtful willingness of a physician to participate in constructive problem solving.

Attention has already been drawn to the perhaps more difficult problems presented by a number of the temporal lobe epileptics in their interseizure personality disorders. They are sometimes quite difficult patients to work with, but they benefit both in their life adjustment and in their seizure frequency from a thoughtful, formal psychotherapeutic relationship, which may be much more directive and controlling than insight-producing.

As for the unique psychiatric problems presented by the epileptic, two medication notes may be in order. First, already alluded to in cases of protracted petit mal or in cloudy and confused states in general, the central problem is one of a low level of arousal of the central nervous system, often commented on by the patient, who is aware that he can abort a seizure or prevent an anticipated one by heightening his state of attention. In such conditions, where medication rather than just sensible management is called for, amphetamine and amphetamine-like compounds are much more likely to be effective than sedatives. Secondly, in the disturbed psychomotor epileptic—whether manifesting one of the acute psychotic states described or just interictal irascibility, aggressivity, and impulsiveness—the use of phenothiazine tranquilizers is highly effective. Apparently, these are often avoided because of the evidence that the phenothiazines may be epileptogenic. But in these cases—

particularly those cases that show forced normalization of the EEG during the disturbed period—adequate phenothiazine medication is desirable and often effective.

Surgical intervention. When focal seizures are a manifestation of identifiable structural pathology and good medication control of the seizures is not obtained or the pathological process is itself progressive, surgical ablation is indicated, provided it does not lead to crippling effects, such as aphasia, major hemiparesis, etc.

Of special interest is the problem of surgery in the temporal lobe epileptic. These patients are very difficult to control with medication, and a number of them may have very disturbed lives as a result of their seizures or their interseizure dysfunction. Penfield on this continent, Falconer in England, and others around the world have demonstrated that ablation of the anterior temporal lobe can be an effective therapeutic measure in curing or at least making amenable to pharmacotherapy a number of temporal lobe epileptics. The procedure is not without hazard, but in recent years several modifications have been developed that promise to be of use. At Massachusetts General Hospital, for example, the use of implanted electrodes for precise focal diagnosis and later focal ablation without gross resection of the temporal lobe has seemed to be of value. Strategically similar though explicitly different maneuvers have been carried out by Turner in England and by Talairach in France, with considerable success and with far less hazard than the open resection. There are many considerations involved in the selection of patients for these procedures, but it should be emphasized that surgery is no longer a course of last resort in the psychomotor epileptic. It should be considered actively in his evaluation if there is any concern about medical control. Neurosurgical advice should, of course, be sought in making this evaluation.

Deserving of final mention is an even more experimental procedure described primarily by Jinnai et al. in Japan. They have described the use of focal lesions in the region of the fields of Forel in the treatment of patients with grand mal seizures. They reported encouraging success both in seizure control and in alleviation of the electrophysiological abnormalities seen in the EEG. This procedure is as yet without firm physiological basis, but should this interesting possibility be successfully pursued, it may be possible to offer therapeutic surgery to a wider spectrum of intractable epileptics than heretofore.

Suggested Cross References

Further material on the convulsive disorders may be found in Laufer's section on the brain-disordered child (Section 42.3), which includes a discussion of the epileptic child; in Cytryn and Lourie's chapter on mental retardation (Chapter 22); and in Solomon's chapter on neurology (Chapter 10), which contains an

alternate classification of epilepsy. Information regarding the fundamental neurophysiology and neuroanatomy and the neurochemistry of epilepsy is presented in Sections 2.5 to 2.9 and 2.2, respectively, in Area B. In that same area see Rainer's section on genetics (Section 2.1), with special reference to genetic counseling. For more detailed discussions of hysteria and schizophrenia, which were mentioned here in reference to the differential diagnosis of epilepsy, see Section 23.2 and Chapter 15, respectively.

Chapter 22

Mental Retardation

22.1 • • •

LEON CYTRYN, M.D.

REGINALD S. LOURIE, M.D.

Introduction

Recent interest in mental retardation. Mental retardation may be viewed as a medical, psychological, or educational problem, but in its final analysis it is primarily a social problem. This explains the fact that throughout history the attitude toward the mentally retarded often reflected the general social attitudes of a given people or a given culture.

In more modern history there were three distinct junctures characterized by great public interest and professional creative thinking in the field of mental retardation. Characteristically, they all followed crucial periods of great social upheaval, resulting in a popular adoption of gradually more liberal, more truly democratic attitudes toward society's less fortunate members, including the mentally retarded.

The first germinal period in the field of mental retardation coincided with the time of the French and American Revolutions and the ideas of equality and rights for all men, which upset the feudal, vertical social structure. The times of Itard and his pioneering labors were also the times of Pinel, who unchained the insane, and the beginning of a popular vote and social legislation.

The second period followed the revolutions that swept Europe in 1848, in the wake of which a further liberalization of public opinion and gradually increasing legislative justice took place. In such a favorable climate, the ideas of Guggenbühl, Séguin, and Howe about special educational opportunities for the mentally retarded spread rapidly throughout Europe and North America.

The third, our present period, in turn followed the cataclysm of World War II. The great resurgence of professional and public interest in mental retardation and its sudden respectability are the result of several,

not necessarily related, factors. Again, probably the most important was the radical change in the social climate felt everywhere on the local, national, and international level. As if to atone for letting the ravages of World War II happen, the postwar trend has been toward securing equal rights and opportunities for all human beings, including the traditionally downtrodden. These include the colonial nations of Asia and Africa, racial and religious minorities everywhere, the old, the very young, the poor, and the sick. Government involvement in an increasing range of social issues has become universally accepted, despite some opposition of advocates of laissez-faire policies of the past.

Thus, the social climate has been favorable for overcoming the traditional public inertia regarding mental illness and mental retardation. Suddenly, the retarded were viewed as individuals with inherent needs and rights. Various civic groups became champions of those rights in the forum of the federal, state, and local governments. In the United States, in the best American tradition of self-help, the National Association for Retarded Children, founded in the 1950's by groups of parents of retarded children, has been the *spiritus movens* of the radical change in public opinion in favor of the retarded.

Historical survey

Early attitudes. There is very little information about the problems of mental retardation in antiquity, in medieval times, and even in modern history up to the beginning of the 19th century. We find only scanty references scattered among ancient religious and medical writings, indicating some awareness of the problem. Hippocrates mentioned anencephaly and other cranial malformations associated with severe retardation. The laws of Sparta and ancient Rome included provisions for extermination of severely retarded children in infancy, a practice revived recently during the infamous Nazi regime.

In medieval Europe the mentally retarded were at best tolerated as jesters and freaks of nature and at worst considered to be evil creatures, in alliance with the devil. This latter belief was particularly popular during the Reformation. In contrast, Asian religious

leaders such as Confucius in China and Zoroaster in Persia advocated humane treatment of the mentally retarded in their teachings. Jewish Talmudic scholars exempted the mentally retarded from criminal responsibility.

The era of humanism saw more interest on the part of the church authorities and the beginning of a more protective attitude. This interest was not shared, however, by the scientific and medical community, as attested by the conspicuous absence of any writings on mental retardation up to the beginning of the 19th century. Mental retardation was often considered a variant of insanity, and it was not until 1689 that Locke made a clear distinction between the two.

Nineteenth century attitudes. The spirit of the French Revolution heralded the beginning of efforts to rectify all kinds of social injustices and to put an end to the subhuman treatment of the mentally retarded. Significantly, the medical profession became caught up in the spirit of the times, and this led to pioneering work of several of its members. In the early part of the 19th century, Itard in France laid the groundwork for the future development of the education and training of the mentally retarded through his patient efforts with the wild boy of Aveyron.

In the middle of the 19th century, Guggenbühl in Switzerland introduced the idea of institutional treatment of the mentally retarded. His meteoric rise to fame gave impetus to the establishment of special educational institutions for the retarded, first throughout Europe and then in the United States and Japan. Guggenbühl's naive notions that the diverse forms of mental retardation were only expressions of cretinism and his promise of total cure (which prompted his downfall) should not detract from his contribution to the field. He made mental retardation a respectable field of medicine and educational endeavor and established special institutions for the mentally retarded throughout the civilized world.

Séguin published the first textbook in this field, *The Physiological and Moral Instructions of Idiots*. After his emigration to the United States in 1848, he contributed greatly to the fruitful, pioneering activity in this country in the field of mental retardation.

Howe, through his efforts to legislate state support for the care and instruction of the feeble-minded, helped the development of institutional care throughout the United States and Canada. By taking a realistic approach to the limitations of special education, Howe wisely avoided the pitfalls experienced by Guggenbühl.

Unfortunately, the enthusiasm of the early and middle parts of the 19th century, which led to the establishment of institutions for retarded children as places of learning and instruction, gave way to a pessimistic attitude in the latter part of the 19th century. This was probably a result of the great dis-

appointment felt when the promises of the early pioneers for total reversibility or cure of mental retardation failed to materialize. The emphasis was then put on vocational rather than scholastic aspects of training and on concentration of effort on the mildly retarded, to the exclusion of the more severely afflicted group. The change in attitude also affected the character and goals of the institutions for the mentally retarded. They were viewed no more as means of rehabilitation and education but rather as means of isolating the mentally retarded from the mainstream of community life. This trend was reinforced by several pseudoscientific speculations, which cloaked in modern terms the medieval concept of the inherent "badness" of the mentally retarded.

The efforts of the medical profession during this period were largely diverted from fruitful research and were directed toward finding ways of checking the menace of mental retardation by various means of eugenic control, ranging from sterilization to euthanasia and, more recently, birth control. The physicians remaining in the field, like their counterparts in mental hospitals, became isolated from academic centers of learning and research, since their subject was not deemed worthy of scientific investigation.

Twentieth century attitudes. The beginning of the 20th century witnessed the perpetuation of professional lethargy, but there were forces afoot that, in time, brought about a radical change, a renewed aura of scientific respectability, and indeed an unprecedented appeal, with everybody clamoring to get on the bandwagon. Several crucial discoveries may be credited for this unusual phenomenon. Garrod's concept of the inborn errors of metabolism was probably the first in the chain of significant events that attracted the curiosity of the medical academic community. Fölling's discovery of phenylketonuria in 1934 helped to popularize Garrod's concepts and in time pointed to possibilities of preventing mental retardation by circumvention or avoidance of the defective metabolic pathways. The same was true of the unraveling of the metabolic defect in galactosemia, which was followed by the detection of a host of other metabolic disorders. The genetic principles elaborated by Mendel and improvement in laboratory techniques gave impetus to the development of the rapidly expanding science of genetics. Improvements in obstetrical techniques, control of syphilis, and the discovery of Rh incompatibility, soon followed by the introduction of exchange transfusions, were among other important factors that suddenly opened new, exciting vistas in the field of mental retardation for the medical researcher and clinician alike.

A favorable public opinion coupled with the enthusiastic endorsement by the scientific community could not fail to bring about a radical, positive approach to the problem of mental retardation. One

civilized country after another adopted new laws and introduced means to further research and ensure the welfare of the mentally retarded. The United States actually lagged behind many countries on both sides of the Iron Curtain, especially when it came to the provision of decent facilities for care and education. Even today, many state institutions for the mentally retarded are a festering sore, an ugly medieval relic in this most affluent country.

However, in the early 1960's, under the direction and initiative of the late President Kennedy, a thorough program was prepared by a panel of experts. It addressed itself to the complexities of the problem and made sweeping recommendations that were, in part, adopted through ordinary legislative channels. Governmental support, favorable public opinion, and research opportunities keep attracting an increasing number of physicians to the field of mental retardation. To use a metaphor, mental retardation was the ugly maiden who was kept in the attic for a long time. Suddenly, suitors have begun to arrive in numbers, since they discovered that the prospective bride is not so homely after all, and, in addition, she now has a handsome dowry.

Problems of definition, nomenclature, and classification. The problem of adopting a universally acceptable system of defining and labeling mental retardation has long vexed many individual workers in this field and lately has attracted the attention of national and even international scientific and governmental bodies. The still existing confusion may be attributed primarily to the complexity of the problem of mental retardation, which defies simple conceptualization.

Definition. The biomedical and sociocultural adaptational models represent the two major approaches to the conceptual definition of mental retardation. The adherents of the former in our country and in the U.S.S.R. insist on the presence of basic changes in the brain as a *sine qua non* in the diagnosis of mental retardation. The proponents of the latter, on the other hand, emphasize the social functioning and general adaptation to accepted norms. Each of these approaches has many ramifications that complicate the issue even further.

Brain damage may be viewed as a demonstrable anatomical lesion, an alteration of the basic constituents of the brain tissue, a metabolic disturbance of the nerve cell, diminished capacity for interneuronal impulse transmission, or a combination of all these factors.

The sociopsychological approach focuses on the developmental impairment in infancy and preschool years, on learning difficulties in school age, and on poor social-vocational adjustment in adulthood. The prevailing cultural norms against which an individual's performance will be judged, rather than his neuropathology, may be decisive in defining the degree of social inadequacy, that is, the inability to

learn and adapt to the demands of a society and to be self-sufficient. Thus, individuals classified as mentally retarded in our technological, complex society might have been competent and successful in a more primitive and intellectually less demanding environment.

There is no known technique for *direct* assessment of intelligence or intellectual potential, nor is there a correlation of the latter with anatomical and functional impairment of the central nervous system. It is futile, therefore, with our present knowledge, to view mental retardation in a unidimensional frame of reference. Rather, it has to be considered as a multidimensional phenomenon that involves overlapping physiological, psychological, medical, educational, and social aspects of human functioning and behavior. This broader view is reflected in the definition of mental retardation adopted by the American Association on Mental Deficiency in 1961: "Mental retardation refers to sub-average general intellectual functioning which originates in the developmental period and is associated with impairment in adaptive behavior." This description circumvents the question of etiology, the problem of nature versus nurture, and the clinical course of mental retardation, that is, its treatability or even curability. Because of the avoidance of these highly controversial areas, it provides a useful, practical, operational definition acceptable to all disciplines.

Nomenclature. Mental deficiency, which is the term used in the American Psychiatric Association's manual on terminology and classification to designate subaverage intellectual functioning, is often used interchangeably with mental retardation. Recently, however, the World Health Organization recommended the use of the term mental subnormality, which in turn is divided into two separate and distinct categories: mental retardation and mental deficiency. According to this nosology, mental retardation is reserved for subnormal functioning due to environmental causes in the absence of central nervous system pathology, and mental deficiency describes subnormal functioning due to pathological causes. Mental deficiency is also used often as a legal term, applied to people with an I. Q. below 70.

The term feeble-mindedness was often used in American literature in the past and is still in use in Great Britain, where it generally denotes the milder forms of mental retardation. Oligophrenia is in common use in the U.S.S.R., Scandinavia, and some other Western European countries. Amentia appears only infrequently in modern psychiatric literature.

Our choice of the term mental retardation only reflects the widest preference of all professional groups.

Classification. The pluridimensional character of mental retardation is also reflected in the various approaches to classification of this condition. Essentially, they all deal with the developmental characteristics, potential for education and training, and

TABLE I
Developmental Characteristics of the Mentally Retarded¹

This table integrates chronological age, degree of retardation, and level of intellectual, vocational, and social functioning.

Degree of Mental Retardation	Preschool Age 0-5 Maturation and Development	School Age 6-20 Training and Education	Adult 21 and over Social and Vocational Adequacy
Profound	Gross retardation; minimal capacity for functioning in sensorimotor areas; needs nursing care	Some motor development present; may respond to minimal or limited training in self-help	Some motor and speech development; may achieve very limited self-care; needs nursing care
Severe	Poor motor development; speech minimal; generally unable to profit from training in self-help; little or no communication skills	Can talk or learn to communicate; can be trained in elemental health habits; profits from systematic habit training	May contribute partially to self-maintenance under complete supervision; can develop self-protection skills to a minimal useful level in controlled environment
Moderate	Can talk or learn to communicate; poor social awareness; fair motor development; profits from training in self-help; can be managed with moderate supervision	Can profit from training in social and occupational skills; unlikely to progress beyond 2nd grade level in academic subjects; may learn to travel alone in familiar places	May achieve self-maintenance in unskilled or semiskilled work under sheltered conditions; needs supervision and guidance when under mild social or economic stress
Mild	Can develop social and communication skills, minimal retardation in sensorimotor areas; often not distinguished from normal until later age	Can learn academic skills up to approximately 6th grade level by late teens; can be guided toward social conformity	Can usually achieve social and vocational skills adequate to minimum self-support but may need guidance and assistance when under unusual social or economic stress

¹ Adapted from *Mental Retardation Activities of the U. S. Department of Health, Education, and Welfare*, p. 2. United States Government Printing Office, Washington, 1963.

social and vocational adequacy. The degrees or levels of retardation are expressed in various terms. The American Psychiatric Association uses the terms mild mental deficiency (I.Q. 70 to 85), moderate mental deficiency (I.Q. 50 to 70), and severe mental deficiency (I.Q. below 50). The following terms are recommended by the World Health Organization: mild subnormality (I.Q. 50 to 69), moderate subnormality (I.Q. 20 to 49), and severe subnormality (I.Q. 0 to 19). The American Association on Mental Deficiency adopted the terms borderline (I.Q. 70 to 84), mild (I.Q. 55 to 69), moderate (I.Q. 40 to 54), severe (I.Q. 25 to 39) and profound (I.Q. 0 to 24) (see Table I). The terms idiot, imbecile, and moron still enjoy some popularity in Europe but are seldom used in the United States. (See Table I.)

Epidemiology

It is estimated that 3 per cent (5,400,000) of the U.S. population are mentally retarded. This often quoted estimate is only approximate, since there are no precise data available, except in a few areas of the country.

The distribution of mental retardation is uneven in different age groups. In the preschool years, only about 1 per cent of the population are diagnosed as mentally retarded, since only the severe forms of this disorder are recognized on routine examination. The highest incidence is found in school-aged children, with the peak at ages 10 to 14. This reflects the close supervision and continuous evaluation of the children's intellectual and social performance in a school

setting, with availability of standards of academic performance and the use of standardized intelligence tests. The inadequacy of these yardsticks for future life performance is attested to by the abrupt drop in the frequency of mental retardation after school age, when most of those who were identified as mentally retarded blend into the general population.

The overwhelming majority (87 per cent) of the mentally retarded fall into the mild category, and the remainder (13 per cent) belong to the moderate, severe, and profound groups.

Roughly 126,000 children born each year in this country are expected to be mentally retarded. It is estimated that of the total number of mentally retarded only about 60,000 to 90,000 belong to the severely and profoundly retarded categories; they require custodial care in a sheltered environment. The moderately retarded group numbers about 300,000 to 350,000; they can be trained in self-care, rudiments of social adjustment and judgment, and sometimes performance of simple productive tasks in a sheltered environment. These groups provide the bulk of mentally retarded individuals in institutions. The mildly retarded group includes roughly 5,000,000 people; they can be educated to a limited extent and are potentially able to adjust, at least marginally, to the demands of society and to employment. This group comes predominantly from the lower socioeconomic strata of our society, and it is believed that many of its members are retarded due to environmental deprivation. The lower socioeconomic groups also supply a disproportionately large number of the moder-

ately and severely retarded, but the discrepancy in these groups is not so great as in the mildly retarded group. There seems little doubt that more stringent developmental evaluation of preschool children and more uniform school standards would result in a far greater number of children identified as moderately retarded in the preschool and school age population.

Etiology and Syndromes

Prenatal factors. Since Garrod's original description of alkaptonuria in 1908, the inborn errors of metabolism have commanded the attention of researchers and clinicians, exceeding by far their relative frequency. The total of all the hereditary metabolic defects probably accounts for about 4 to 5 per cent of mental defectives, but the lessons already learned from the study of these disorders point to exciting diagnostic, therapeutic, and preventive possibilities. The introduction of paper chromatography played a major role in the rapid growth of the list of known amino acidurias, and several ingenious but rather simple methods allow for routine mass screening of large populations for biochemical abnormalities. Tolerance tests with suspect substances or related compounds permit the detection of heterozygous carriers and individuals with a milder form of a disease. Further biochemical research may bring the number of metabolic disorders to 10 per cent of the mentally retarded group.

The success of dietary measures in phenylketonuria (PKU), maple syrup disease, and galactosemia represent a major triumph in the medical treatment of mental retardation, which hitherto operated on a hit or miss basis. Although the mechanism of injury to the central nervous system in these disorders is not known, it is believed to be a result of abnormal accumulation of metabolites. The therapy is based on the principle of dietary omission or reduction of a specific dietary ingredient that cannot be properly metabolized because of a specific enzymatic block. This in turn helps to eliminate the abnormal accumulation of the metabolites, thus avoiding the potential injury to the central nervous system. Another therapeutic approach consists of dietary *addition* of essential metabolites, such as the addition of cystine in homocystinuria.

The intensive research in the area of the inborn errors of metabolism promises an increased understanding of normal and abnormal cerebral functioning. The exact role of various enzyme systems in the brain during various stages of embryogenesis and in the first few years of life is still unknown, but many exciting clues still await further clarification. The apparent simplicity of a single metabolic block is deceptive, since the accumulation of a metabolite leads to a sequence of secondary and tertiary events. Each of these events, singly or in combination, may be responsible for the ultimate damage to the de-

veloping brain. Too much or too little of a normal compound or the presence of an abnormal one may be involved. This exciting search, potentially of great significance to the entire field of mental illness, is facilitated by the fact that several inborn errors of metabolism, such as PKU and galactosemia, can be approximated in animals by feeding them large amounts of phenylalanine or galactose, without, of course, reproducing the basic enzymatic defect.

Finally, the recent advances in tissue and organ transplant hold out an exciting possibility of direct treatment of congenital enzymatic defects by transplanting enzyme-producing tissue, such as liver, from a normal donor to the affected individual, thus meeting the challenge head on instead of circumventing it.

Disorders of amino acid metabolism

Phenylketonuria (PKU). First discovered by Fölling in 1934, phenylketonuria has become known as the inborn error of metabolism associated with mental retardation par excellence. The intensive study of its many aspects with the attendant publicity was greatly responsible for the recent interest of the medical community in mental retardation. The information gained from the study of PKU serves as a model of investigation of other hereditary biochemical disorders, which has already led to the discovery of a host of inborn enzymatic defects.

PKU is transmitted as a simple recessive autosomal Mendelian trait. Its frequency in the United States and various parts of Europe ranges between 1 in 10,000 to 1 in 20,000. Although the disease is reported predominantly in people of North European origin, sporadic cases have been described in Negroes, Yemenite Jews, and members of Mongolian races. The frequency among institutionalized defectives is about 1 per cent.

The basic metabolic defect in PKU is an inability to convert phenylalanine, an essential amino acid, to tyrosine because of the absence or inactivity of the liver enzyme phenylalanine hydroxylase, which catalyzes this conversion. This in turn gives rise to several abnormal biochemical findings, such as: (1) elevated phenylalanine in the blood (10 to 25 times normal) and cerebrospinal fluid, excretion of an abnormal metabolite, phenylpyruvic acid, in the urine as well as phenylalanine (30 to 50 times normal) and several derivatives; (2) a related disturbance of tryptophan and tyrosine metabolism, leading to a marked decrease in serum serotonin and lower than normal blood levels of epinephrine and norepinephrine.

The majority of patients with PKU are severely retarded, but some patients are reported to have borderline or normal intelligence. Eczema and convulsions are present in about a third of all cases. Electroencephalogram (EEG) is abnormal in about 80 per cent, even in patients without convulsions, showing irregular spike and wave discharges. The majority of patients are undersized, and the head tends to be small. Although the clinical picture varies, typical PKU children are hyperactive and exhibit erratic, unpredictable behavior, which makes them difficult to manage. They have frequent temper tantrums and often display bizarre movements of their bodies and upper extremities and twisting hand mannerisms that sometimes resemble the behavior of autistic or schizophrenic children. Verbal and nonverbal communication is usually severely impaired or nonexistent. Coordination is poor, and perceptual difficulties are many. The original description of PKU patients as blond and blue-eyed (due to a relative deficiency of melanin, a by-product of tyrosine) applies to some, especially in the younger age group.

The best known screening test depends on the reaction of phenylpyruvic acid in the urine with ferric chloride solution to

give a vivid green color. This test has its limitations, since it may not become positive until the baby is 5 or 6 weeks old and it may be positive in other amino acidurias. Another screening method, commonly used, is the Guthrie test, which measures the phenylalanine level in the blood, using a bacteriological procedure. In addition to these simple screening methods, there are several chromatographic and biochemical tests available for the purposes of individual management and research.

Early diagnosis is of extreme importance, since a low phenylalanine diet, in use since 1955, results in significant improvement in both behavior and developmental progress. The best results seemed to be obtained with early diagnosis and the start of the dietary treatment prior to 6 months of age. The attainment of even normal or near normal intelligence is possible if the dietary treatment is begun before 3 months of age. In addition, children on this diet become more responsive, less hyperactive, and much easier to manage. There is also an improvement in the EEG pattern and a diminution or cessation of seizures.

Dietary treatment is not without dangers. Phenylalanine is an essential amino acid, and its complete omission from the diet may lead to such severe complications as anemia, hypoglycemia, edema, and even death. The problem has become more complicated with the recent knowledge of patients with elevated phenylalanine levels in the blood, as picked up on screening tests, who do not seem mentally retarded and do not excrete phenylpyruvic acid in their urine but do have a relatively low tolerance for phenylalanine. When these infants are not monitored well while on dietary treatment, resulting in low blood levels, they are likely to develop serious complications from phenylalanine depletion. It remains to be clarified whether this condition represents an independent entity, phenylalaninemia, or a partial or arrested form of PKU, due perhaps to the influence of a modifying gene. At any rate, it points out the importance of caution and careful follow-up in the diagnosis and treatment of PKU and other metabolic disorders.

Dietary treatment of PKU can often be discontinued at the age of 5 or 6 years, although no alternate metabolic pathways capable of keeping the blood phenylalanine levels in normal range have been discovered as yet. Sometimes, however, withdrawal of the diet results in deterioration of behavior and recurrence of seizures. Evaluation of the dietary benefits is further complicated by the fact that some PKU children have normal or near normal intelligence and behavior on a normal diet.

The parents of PKU children and some of these children's normal siblings are heterozygous carriers and can be detected by a phenylalanine tolerance test, which may be of great importance in genetic counseling of these people.

The exact mechanism of the brain damage in PKU is still unknown. Some researchers think that the high phenylalanine concentration interferes with the usual respiration of brain tissue or normal functioning of essential enzyme systems. Of particular psychiatric interest are the hypotheses that link both the mental deficiency and the behavioral abnormalities in PKU to the related disturbance in tryptophan metabolism, notably serotonin deficiency. However, the role of serotonin both in PKU and in psychotic disorders is still controversial and must await further clarification through careful biochemical and behavioral studies.

Maple syrup disease (Menkes disease). First discovered by Menkes in 1954, maple syrup disease is an inborn error of metabolism transmitted by a rare single autosomal recessive gene. The biochemical defect interferes with the decarboxylation of the branched chain amino acids: leucine, isoleucine, and valine. As a result, these amino acids and their respective keto acids accumulate in the blood and cause overflow amino aciduria. The urine has a characteristic odor, which gave the condition its name and which is due to the derivatives of the keto acids.

The diagnosis can be suspected by the use of ferric chloride

or dinitrophenylhydrazine, each of which interacts with the urine to give, respectively, a navy blue color or a yellow precipitate. The pathological changes are relatively minimal and consist mainly of poor formation of myelin in the brain.

The clinical symptoms appear during the 1st week of life. The infant deteriorates rapidly and develops decerebrate rigidity, seizures, respiratory irregularity, and hypoglycemia. If untreated, most patients die in the first months of life, and the survivors are severely retarded. Some variants have been reported, with transient ataxia and only mild mental retardation.

Treatment follows the general principles established in PKU and consists of a diet very low in the three involved amino acids. The reports to date are very encouraging, indicating the possibility of fairly normal physical and intellectual growth of patients on the dietary regimen.

As in PKU, the exact nature of brain damage is still not clear.

Hartnup disease. This rare disorder took its name from the family in which it was detected. Like the preceding diseases described, it is transmitted by a single recessive autosomal gene. The symptoms are intermittent and variable and tend to improve with age. They include a photosensitive pellagra-like rash on extension surfaces, episodic cerebellar ataxia, and mental deficiency. Of particular importance to psychiatrists is the fact that transient personality changes and psychoses may be the only manifestation of the disease, and these milder cases do not come to medical attention until late childhood or adolescence.

The metabolic defect involves defective tryptophan transport, and biochemical findings consist of a marked amino aciduria and increased excretion of indican and indole derivatives. The diagnosis can be made by paper chromatography of the urine.

Treatment with nicotinic acid and antibiotics such as neomycin may relieve the skin rash and possibly the ataxia, but it does not affect the mental retardation.

Citrullinuria. This is one of three recently described rare disorders involving the urea cycle. It probably involves an enzymatic defect in the conversion of citrulline into argininosuccinic acid. As a result, the level of citrulline in the blood, cerebrospinal fluid, and urine is elevated. The disorder is accompanied by mental retardation.

Hyperammonemia. This is another rare defect involving urea synthesis, probably resulting from a metabolic block in the conversion of ornithine to citrulline. The serum ammonia is elevated, and mental retardation has been reported.

Argininosuccinic aciduria. This third disorder of the urea cycle is as rare as the two preceding ones. The biochemical defect involves a block in the conversion of argininosuccinic acid to arginine in the brain. As a result, the argininosuccinic acid is elevated in the cerebrospinal fluid and to a lesser extent in the blood and urine.

The clinical manifestations include mental retardation, grand mal seizures, brittle white hair, and intermittent coma.

All three disorders of the urea cycle are being experimentally treated with a low protein diet.

Idiopathic hyperglycinemia. The biochemical findings in this rare condition consist of a marked elevation of the blood and urine glycine levels. Ingestion of leucine by the patient precipitates ketosis. The nature of the metabolic defect is unknown as yet.

The clinical picture is characterized by intermittent vomiting and ketosis, severe mental deficiency, and choreoathetosis. In contrast, the commoner condition, glycinuria, is not usually accompanied by mental disability. Dietary therapy is now in the experimental stage.

Histidinemia. This defect in histidine metabolism is transmitted by a single autosomal recessive gene and involves a block in the conversion of histidine to urocanic acid resulting from histidase deficiency. This in turn leads to an elevated histidine level in serum and urine. The urine also contains

imidazole pyruvic, imidazole lactic, and imidazole acetic acids in increased amount, which give a positive ferric chloride test (green).

Mild mental retardation and sometimes speech defect are a part of the clinical picture.

Homocystinuria. The metabolic defect in this rare disorder consists of a reduction or absence of cystathionine synthetase activity. Homocystine is excreted in the urine. The patients have an odd appearance and are mentally retarded. Subluxation of the lens of the eye is a characteristic clinical feature. Therapy is still in the experimental stage and involves the addition of cystine to the diet.

Lowe's oculorenal dystrophy. This disorder, transmitted by an autosomal recessive gene, presents a varied clinical picture that includes some of the following eye defects, buphthalmos, microphthalmos, cataracts, and corneal opacities. The renal ammonia production is decreased, and a generalized amino aciduria is found.

Cystathionuria. The metabolic defect in this disease consists of a block at the site of cleavage of cystathionine to cysteine and homoserine. Cystathionine is found in the urine, and the patients are mentally retarded.

Hyperprolinemia and Oast-House disease. These are two further examples of rare amino acidurias associated with mental retardation. The number of known amino acidurias will no doubt continue to increase as more retarded and brain-damaged individuals have their blood and urine studied by chromatographic methods.

Disorders of fat metabolism. It is generally assumed that disturbances in lipid metabolism related to the central nervous tissue are genetically determined, resulting from an enzymatic defect. The exact nature of the enzymatic blocks and their localizations in the chemical chain of reactions are still unknown. However, the nature of the various metabolic products causing injury to the various components of the central nervous system (CNS) has been determined by biochemical analysis in most of the disorders discussed below. These can be roughly divided into two groups: the first includes diseases characterized by an increase and storage of lipids in the CNS, and the second involves diseases characterized by a decrease in lipids in the CNS, resulting in demyelination.

There are several hypotheses as to the nature of the metabolic disorder in the diseases involving accumulation of lipids in the tissue. (1) Normal lipid is produced at an excessive rate. (2) The normal lipid is produced at a regular rate, but an abnormality in the end organ tissues results in accumulation. (3) An abnormal lipid is produced. Specific enzymatic defects have been recently demonstrated in some of these disorders.

Cerebromacular degenerations. The cerebromacular degenerations represent a group of disturbances in which there is progressive mental deterioration and loss of visual function. They are all transmitted by an autosomal recessive gene. The four types of cerebromacular degeneration differ as to the age of onset. The earliest one, Tay-Sachs disease, occurs chiefly among Jewish infants, particularly those from Eastern Europe; the others are found in members of all races.

The accumulation of lipid substances, that is, gangliosides, in neurons (the nerve cells) throughout the CNS is a characteristic showed by all forms of this disorder. In the Tay-Sachs vari-

ant, there is also an accumulation of gangliosides in the ganglion cells of the retina; in others the ganglioside deposits are found in the outer retinal layers.

The gangliosides can be chemically identified after brain or rectal tissue is obtained by biopsy. Neuraminic acid, a characteristic component of gangliosides, is elevated in the brain tissue but not in the spinal fluid.

Tay-Sachs disease begins in infants 4 to 8 months of age. The infants become hypotonic, slow down in their developmental progress, and become weak and apathetic. In addition, there are spasticity, accompanied by persistent primitive postural reflexes, cherry red spots in the macula lutea of each retina, convulsions, and progressive physical and mental deterioration leading to death in 2 to 4 years.

The Jansky-Bielschowsky type, also called the early juvenile or late infantile form of cerebromacular degeneration, has its onset at 2 to 4 years of age. There is a pigmentary degeneration of the macula and progressive dementia.

The juvenile form, Spielmeier-Stock-Vogt-Koyanagi, occurs in early school-aged children. This variant is characterized by a much slower degenerative process and usually starts at the age of 5 or 6 years when impairment of vision appears as the first symptom. The impairment is progressive and leads to blindness due to the atrophy of the optic nerve and pigmentary degeneration of the macula. Ataxia, convulsions, and mental deterioration complete the picture. The course is protracted over a period of 10 to 15 years.

The late juvenile form, Kuf's disease, is rare and occurs after 15 years of age.

All these variants of cerebromacular degeneration are progressive, and there is no treatment available to date.

Niemann-Pick disease. This disease is transmitted by an autosomal recessive gene and occurs predominantly in Jewish infants.

The biochemical defect involves storage of sphingomyelins in the neurons, liver, and spleen, which can be identified by biopsy of the rectum or the brain. The blood and the bone marrow contain foam cells and vacuolated leukocytes. Brady demonstrated recently the reduction of activity of a specific enzyme that catalyzes the hydrolysis of sphingomyelin in tissues of patients with Niemann-Pick disease.

The clinical picture consists of a developmental arrest and mental regression accompanied by abdominal enlargement due to hepatosplenomegaly, anemia, general emaciation, and occasionally a cherry red spot in the retina, similar to that found in Tay-Sachs disease. The onset is usually in infancy, following an initially normal development. Occasional cases have a later onset and a relatively slow chronic course, characterized by ataxia and a lesser degree of mental deficiency. No treatment is known at present, and death occurs in most cases in early childhood, before the age of 4.

Gaucher's disease. This lipidosis also occurs mostly in Jewish children and has an autosomal recessive mode of genetic transmission.

The metabolic abnormality, as shown by Brady et al., consists of a diminution of enzyme activity, namely of the enzyme that catalyzes the breakdown of glucocerebroside. This leads to an accumulation of the cerebroside kerosin in the neurons and in the cells of the reticuloendothelial system. Characteristically, there is an accumulation of Gaucher cells, that is, large, pale, round cells filled with kerosin, first in the reticuloendothelial system and then in other tissues. The demonstration of these Gaucher cells in the bone marrow or in biopsy material from the brain or rectum serves as a diagnostic proof of this disease. Clinically, the illness occurs in two forms.

The acute infantile form has its onset in infancy, following several months of normal development, and is characterized by progressive mental deterioration and developmental arrest. Hepatosplenomegaly, abdominal and cranial enlargement, hypotonia, and opisthotonus complete the clinical course, which is usually fatal before the end of the 1st year of life.

The chronic form has an insidious onset, usually any time before the 10th year of life, but occurs occasionally in adolescents and young adults. There is less or no involvement of the CNS, and the main clinical symptoms are physical, including hepatosplenomegaly, anemia, thrombocytopenia, and bone changes leading to pathological fractures and severe deformities. The course is chronic, characterized mainly by chronic physical handicaps.

Bigler and Hsia syndrome. This rare disorder is transmitted by an autosomal recessive gene. Its biochemical abnormality consists of an elevation of triglycerides in the blood.

The clinical features include hepatosplenomegaly and mental retardation. No treatment is available.

Progressive leukoencephalopathies. This group consists of several clinical syndromes characterized by a degeneration of the cortical white matter, with the onset varying from infancy to adulthood and even senility. The central pathological feature in all of them is the demyelination of the cerebral white matter, followed by a degeneration of the axon cylinders. In some cases there is an extension of the degenerative process to the cerebellum and the basal ganglia. The histopathological findings may be demonstrable in the biopsy material of the brain.

The genetic mode of transmission is autosomal recessive, except for Merzbacher-Pelizaeus disease, which is transmitted by a sex-linked recessive gene. Schilder's disease may often occur sporadically.

The clinical course is characterized by progressive dementia, developmental regression, hypotonia, spasticity, ataxia, cortical blindness and deafness, convulsions, and paroxysmal attacks of laughing. The nature of the clinical symptoms depends on the localization of the degenerative process. The prognosis is usually hopeless, and no treatment is available.

The four variations of this disorder are not always distinguishable from each other, and their classification is based primarily on the time of onset and the duration of the illness. Sometimes the clinical course is so acute as to suggest an encephalomyelitis. Some cases, however, manifest remissions lasting for years, during which progress of the disease is arrested.

Schilder's disease may begin at any age but is more common in older children and adults. There is demyelination of cerebral white matter to sudanophilic neutral fat. Long tract signs, such as spastic paraparesis or tetraparesis, are usually the first symptoms, followed by cortical blindness and deafness, convulsions, and dementia. Some cases are reported as responding to steroids, but caution is indicated in evaluation of these reports. The disease is chemically identical to, but clinically different from, multiple sclerosis.

In Krabbe's disease the developmental regression begins in the 1st year of life. The biopsy material of the brain contains peculiar multinucleated giant cells, globoid cells containing glycolipids.

Metachromatic leukodystrophy, histochemically, is characterized by demyelination and accumulation of metachromatic sulfatide in the brain and peripheral nerves. The metachromatic material may be demonstrable in the urinary sediment or by Austin's fluff test. The onset is usually in the first 2 years of life, but the disease may begin later, even in adulthood. The clinical course leads progressively to dementia and neurological deterioration.

In Merzbacher-Pelizaeus disease, the onset is usually in the first years of life, beginning with ataxia and nystagmus, followed by a progressive dementia, spasticity, and rigidity.

Disorders of carbohydrate metabolism

Galactosemia. Galactosemia is transmitted by an autosomal recessive gene. Its metabolic defect, detected in 1956 by Kalckar et al., consists of the inability to convert galactose to glucose, because of the enzymatic defect of galactose 1-phosphate uridyl-transferase. This is absent in the liver and in red blood cells, the latter fact being very helpful in substantiating the diagnosis in early infancy.

The urinary findings include the presence of galactose and general amino aciduria. The reducing substances in the urine may be detected by the use of Benedict's solution and Clinitest tablets but not by the use of Tes-Tape, which is specific only for glucose. The heterozygous carriers can be detected by a galactose tolerance test, but the tolerance test may also be abnormal in infants recovering from severe diarrhea and in patients with liver disease or hyperthyroidism.

Galactosemia, like PKU, is a fine example of rewarded combined effort in basic and applied research. The pinpointing of the exact location of the enzymatic defect, circumvention by dietary adjustment, and early detection, which allows for a prevention of serious brain damage, are held out as an example and a promise to researchers in other metabolic disorders.

The clinical manifestations begin after a few days of milk feeding and include jaundice, vomiting, diarrhea, failure to thrive, and hepatomegaly. If untreated, the disease may be fatal within a short time, or it may lead to progressive mental deterioration, associated with cataracts, hepatic insufficiency, and occasional hypoglycemic convulsions.

A galactose-free diet, instituted early, prevents all clinical manifestations and allows normal physical and mental development. Moderate amounts of milk may be reinstituted under careful monitoring at the beginning of school age, since the patients usually develop alternate metabolic pathways of galactose metabolism.

Glycogen storage disease (Van Gierke's disease). There are several forms of this autosomal recessive metabolic disorder of glycogen metabolism, involving several essential enzymes. The variant most frequently associated with mental retardation is the neuromuscular form of glycogenosis characterized by glycogen storage in the nerve cells, muscles, and other tissues, such as of the liver, heart, kidneys, adrenals, and the reticuloendothelial system.

The clinical manifestations usually begin in the neonatal period and include hepatomegaly, failure to thrive, acidosis, frequent hypoglycemic convulsions, and mental retardation. Hypotonia and heart involvement leading to cardiac failure are often encountered. Only symptomatic treatment for this disorder is available.

McQuarrie type of hypoglycemia. The mode of transmission in this metabolic abnormality is autosomal recessive. The major feature is a recurrent hypoglycemia associated with convulsions and coma, caused by a deficiency of alpha cells in the pancreas. The symptoms appear early in life, often shortly after birth, and lead to progressive mental retardation. Therapy with adrenocorticotrophic hormone (ACTH) or glucagon is effective and prevents mental retardation.

Leucine-sensitive hypoglycemia. This rare autosomal recessive condition is characterized by episodic hypoglycemia, associated with coma and convulsions, following ingestion of leucine, an amino acid commonly found in the diet. Mental retardation develops if the condition is not recognized and treated. Hypoglycemia following a leucine tolerance test is diagnostic for this disease. Treatment is dietary and consists of a low protein diet or a leucine-deficient diet.

Fructose intolerance. The genetic pattern is autosomal recessive in this disorder, which is characterized by episodes of

hypoglycemia after the intake of fructose or sucrose. The nature of the biochemical defect is still uncertain but may involve a deficiency in liver aldolase. Mental retardation results in unrecognized and untreated cases but may be prevented by dietary measures, which consist of a replacement of sucrose and fructose by other sugars.

Sucrosuria and hiatus hernia. It is yet uncertain whether this represents a genetic disorder. The characteristic findings include sucrosuria following a normal diet, esophageal hernia, and mental retardation. Omission of sucrose in the diet is not effective in preventing mental deterioration.

Miscellaneous metabolic disorders

Idiopathic hypercalcemia. The pattern of inheritance in this disorder is that of an autosomal recessive trait, and hypersensitivity to vitamin D probably represents the metabolic aberration. The serum calcium is elevated but may be occasionally normal, and suspicion may be ruled out only after three or four determinations.

The clinical features include irritability, mental retardation, a peculiar elfin facial appearance, short stature, hypotonia, hypertension, strabismus, and nephrocalcinosis.

Several therapeutic approaches are in use, of which the maintenance of patients on cortisone is the most commonly used in this country. The more severe form of the illness does not respond to therapy and often leads to early death or progressive mental deterioration.

Hypoparathyroidism. The etiology of hypoparathyroidism is obscure, but a familial tendency has been reported. The onset in most cases is during childhood. Early diagnosis and early institution of treatment may prevent physical and mental deterioration.

The metabolic error consists of a deficient production of parathyroid hormone by the parathyroid gland. Laboratory findings include elevated phosphorus and diminished calcium levels in the blood. Administration of Parathormone restores blood calcium and phosphorus to normal levels, which is of diagnostic value.

The clinical picture is dominated by episodic tetany and tonic convulsions. X-rays may reveal calcifications in the brain with a predilection for the basal ganglia. Symptoms of hypocalcemia and mental deterioration often develop in protracted cases.

Treatment in early recognized cases consists of administration of calcium and vitamin D or A T 10. In untreated cases of long standing, the mental deterioration is irreversible.

Pseudohypoparathyroidism. The metabolic defect in this autosomal recessive disorder resides in the renal tubules. They fail to inhibit reabsorption of phosphorus in response to Parathormone, which is produced in normal quantity. The laboratory findings are similar to those in hypoparathyroidism.

The illness is characterized by tetany, convulsions, intracranial calcifications, a peculiar round face, and many skeletal abnormalities, particularly of the hands. Mental retardation follows the repeated seizures. Treatment includes vitamin D and calcium.

Pseudo-pseudohypoparathyroidism. The autosomal recessive metabolic abnormality still bearing this cumbersome name produces signs similar to pseudohypoparathyroidism, including mental retardation, despite a normal blood level of both calcium and phosphorus. No treatment is available.

Goitrous cretinism. Cretinism as a condition associated with mental retardation has been known since antiquity. Throughout modern history up to the middle of the 19th century, all forms of mental retardation were considered as variants of this condition.

The classical endemic variety occurs in certain regions as a result of iodine deficiency in the diet. Sporadic athyreosis, congenital absence of the thyroid gland, is the common variety in this country and may be caused by transplacental transmission of immune bodies against thyroid from the mother.

FIGURE 1. Inadequately treated cretinism in a 5-year-old boy. (Courtesy of Dr. Richmond S. Paine, Children's Hospital, Washington, D.C.)

Other varieties of sporadic cretinism occurring in individuals with adequate iodine intake have attracted a lot of attention lately. Several variants are described, all resulting in faulty synthesis of thyroid hormone but associated with varying metabolic defects determined by autosomal recessive genes. Listed among the biochemical abnormalities in asymptomatic heterozygous carriers are the absence of dehalogenase, a defect in production of thyroxine in the thyroid gland, and a defect in the deiodinating moniodotyrosine. In some cases associated with deafness, a disposition to various thyroid disorders in the patient's relatives was reported.

The clinical signs in all varieties include hypothyroidism, goiter (except in athyreosis), dwarfism, coarse skin, disturbances in ossification, hypertelorism, and a large tongue (see Figure 1). Mental retardation becomes a part of the clinical picture if the disease is unrecognized and untreated in infancy. This is explained by the essential role that thyroxine plays in the formulation of structural proteins and lipids in the central nervous system during early infancy. The children are sluggish, their voices hoarse, and speech does not develop. Among the laboratory findings are a low basal metabolism rate, depressed protein-bound iodine, and a high cholesterol level. The radioactive iodine uptake is low, except in the variety reported by Stanbury, which is recessively inherited.

Treatment with thyroid extract may avert most of the symptoms if instituted early in life. It is not effective in adult cretins. Endemic goitrous cretinism is treated and prevented by the ingestion of small amounts of iodine.

Crigler-Najjar disease (familial nonhemolytic jaundice). This defect in the bilirubin metabolism in the liver produces a

nonhemolytic jaundice and represents an autosomal recessive trait. The indirect bilirubin in the serum is elevated, which leads to a gradual development of brain damage (kernicterus) and mental deterioration.

Pyridoxine dependency. The exact mechanism in this autosomal recessive disorder is unknown, but it probably involves some enzyme system in which pyridoxine (vitamin B₆) acts as a coenzyme. The affected infants have abnormally high pyridoxine requirements.

The clinical symptoms consist of seizures accompanied by EEG changes beginning toward the end of the 1st week of life. If the condition remains untreated, it results in spasticity and mental deficiency.

The diagnosis may be established by intravenous administration of 100 mg. of pyridoxine, which results in a dramatic cessation of seizures and improvement in the EEG. Therapeutically, the addition of 10 mg. of pyridoxine to the daily diet is required to keep the patient symptom-free.

Wilson's disease (hepatolenticular degeneration). This disorder of copper metabolism has a recessive mode of inheritance. The two variants of this disease, the juvenile and the adult forms, are inherited independently as separate entities.

The biochemical changes are similar in both forms and consist of a diminished blood level of copper-containing ceruloplasmin. This is accompanied by excessive copper deposits in various tissues, chiefly in the liver and the brain. The resulting liver cirrhosis and degeneration of the lenticular nucleus gave the disease its name. Other laboratory findings include an elevated copper excretion in the urine and amino aciduria involving primarily the aromatic amino acids (phenylalanine, tyrosine,

and threonine). The latter is being explained on a basis of kidney damage due to copper deposits or blamed on a defect in a copper-containing enzyme, tyrosinase.)

The heterozygous carriers are asymptomatic but often manifest abnormal levels of ceruloplasmin in the blood and a tendency to various hepatic difficulties. A copper-loading test is available for detection of heterozygous carriers.

The clinical signs in both forms of the disease include cirrhosis of the liver, progressive emotional and mental deterioration, pseudobulbar palsy, fatuous facial expression, spasticity, and a greenish brown ring in the iris (Kayser-Fleischer ring).

The juvenile form begins between the ages of 7 and 15. Inattentiveness in school and dystonia are usually the first signs. This form is usually unresponsive to treatment, since the dystonia is related not to copper deposits but to hepatic dysfunction, which causes brain damage to the basal ganglia. The nature of the relationship between the hepatic disorder and the brain damage, found also in other liver diseases, is unknown.

The adult form usually begins with tremors and dysarthria but may begin with psychiatric symptoms. It has a good prognosis. There are several treatment methods available, all aiming at lowering the serum copper level and increasing the urinary copper excretion. Penicillamine, a copper-chelating amino acid derived from penicillin, is presently the most effective therapeutic agent. Penicillin-sensitive patients may require the concomitant administration of steroids. Dimercaprol (British anti-lewisite; BAL) is also used with fair results.

Gargoylism (Hurler's disease). Most cases of this disorder are transmitted by an autosomal recessive gene, but sex-linked recessive transmission involving only males has also been observed. The basic metabolic disturbance, the nature of which is still unknown, results in the accumulation of a mucopolysaccharide, chondroitin sulfate B, and glycolipids in the brain, liver, spleen, and connective tissue.

The biochemical findings include chondroitin sulfate in the urine and characteristic foam cells in the blood and bone marrow; the lymphocytes contain metachromatic inclusions, and X-rays show several characteristic abnormalities, such as elongation of the sella turcica, beaking of the thoracic spine on the lateral view (kyphosis), club-shaped lower ribs, thickening of the long bones, misshapen metacarpal bones and phalanges, and skull malformations (see Figure 2).

The clinical course is slow and progressive and starts usually at a very early age, leading to death before adolescence. The hepatosplenomegaly causes abdominal enlargement. The stature is dwarfed, and the face acquires a peculiar appearance that gave rise to the name of the disease. The facial characteristics include bushy confluent eyebrows, thick lips, large tongue, and coarse features. The spadelike hands and sometimes hypertelorism and hydrocephalus complete the picture. There is nearly always a progressive mental deterioration, which often precedes the characteristic facial appearance. No treatment is available.

The differential diagnosis may present some problems. The superficial resemblance to cretins is easily ruled out by x-ray findings and by the hepatosplenomegaly as well as biochemical findings. Gargoylism may also resemble Morquio's disease, a hereditary condition characterized by skeletal deformities and dwarfism without impairment of mental development.

Chromosomal aberrations. Lejeune's discovery in 1959 of the existence of 47, instead of 46, chromosomes in patients with Down's syndrome (mongolism) ushered in a new, exciting era of cytogenetic research. The introduction of new, simplified techniques permitted the study of chromosomal patterns in large populations, which led to the discovery of many abnormalities often associated with mental retardation. The degree of mental retardation is usually

FIGURE 2. Two brothers with Hurler's disease (gargoylism). Note the characteristic facies and the hepatosplenomegaly. (Courtesy of Dr. Richmond S. Paine, Children's Hospital, Washington, D.C.)

more severe in autosomal aberrations and milder in sex chromosome aberrations. With the exception of Down's syndrome, the reported number of patients with chromosomal disorders is rather small, but the great scientific interest in their study is due to the hope of finding a key to the mapping of genetic loci for various enzymes, an important step for the better understanding of inborn errors of metabolism and other genetic disorders. There have been some exciting recent findings by Paine and others of deviations in various enzymatic levels in Down's syndrome that may help identify the genetic loci on chromosome 21. Such findings represent another step toward the better understanding of genetic activity and its correlation with clinical findings. Many similar clinical features are found in several seemingly unrelated chromosomal syndromes.

Autosomal disorders

a. Down's syndrome (mongolism): Since the classical description of mongolism by the English physician Langdon Down in 1866, this syndrome has remained the most discussed, most investigated, and most controversial in the field of mental retardation. Its etiology still remains obscure, despite a plethora of theories and hypotheses advanced with variable acclaim in the last 100 years. There is agreement on very few predisposing factors in chromosomal disorders, among them increased age of the mother and possibly increased age of the father and x-ray radiation. The problem of etiology is complicated even further by the recent recognition of three distinct types of chromosomal aberrations in Down's syndrome:

1. Patients with trisomy 21 (3 of chromosome 21 instead of the usual 2), who represent the overwhelming majority of mongoloid patients, have 47 chromosomes, with an extra chromosome 21. The karyotypes of the mothers are normal. A nondisjunction during meiosis, occurring for yet unknown reasons, is held responsible for this disorder.

2. Nondisjunction occurring after fertilization in any cell division will result in mosaicism, a condition in which both normal and trisomic cells are found in various tissues.

3. In translocation, there is a fusion of two chromosomes, mostly 21 and 15, resulting in a total of 46 chromosomes in affected patients, despite the extra chromosome material. This disorder, unlike trisomy 21, is usually inherited, and the translocation chromosome may be found in unaffected parents and siblings. These asymptomatic carriers have only 45 chromosomes.

Recent biochemical studies in Down's syndrome revealed increased levels of galactose 1-phosphate uridyltransferase and of acid and alkaline phosphatases, elevated activity of glucose 6-phosphate dehydrogenase and 5-nucleotidase, and diminished blood serotonin levels. These abnormalities were found only in the trisomic type. The enzyme levels were in the high normal range in the translocation type of the disease, a fact that may differentiate these two varieties without the cumbersome chromosomal studies. These biochemical findings suggest that the surplus genetic material in mongolism results in a derangement of genetic homeostasis, involving many genes or gene complexes. The question of the prime cause of this metabolic derangement awaits further clarification.

The incidence of Down's syndrome in the United States is approximately 1 in every 700 births. Down, in his original description, mentioned the frequency of 10 per cent among all mentally retarded patients. Interestingly enough, the frequency of patients with Down's syndrome in institutions for the mentally retarded today also approximates 10 per cent. In a middle-aged mother (over 32 years), the risk of having a

mongoloid child with trisomy 21 is about 1 in 100, but when translocation is present, the risk is about 1 in 3. These facts assume special importance in genetic counseling. Occasionally Down's syndrome is associated with acute lymphatic leukemia.

The neuropathological findings are limited to a tendency toward embryonic convoluted patterns of the brain, a small cerebellum and brain stem, abnormalities of the pituitary gland and irregular disposition of ganglion cells in the third cortical layer. Cardiac anomalies, particularly septal defects, are often found, as is hypogonadism.

Mental retardation is the overriding feature of Down's syndrome. The majority of patients belong to the moderately and severely retarded groups, with only a minority having an I.Q. above 50. According to many sources, patients with Down's syndrome are placid, cheerful, and cooperative, which facilitates their adjustment at home. The picture, however, seems to change in adolescence, especially in institutions, where a variety of emotional difficulties, behavior disorders, and (rarely) psychotic illnesses may be seen.

The diagnosis is made with relative ease in an older child but is often difficult in newborn infants. The most important signs in newborns include general hypotonia, oblique palpebral fissures, abundant neck skin, small flattened skull, high cheekbones, and a protruding tongue. The hands are broad and thick with a single palmar transversal crease, and the little fingers are short and curve inward (see Figure 3). Moro's reflex is weak or absent.

There are over 100 signs or stigmata described in Down's syndrome, but they are rarely found all in one individual. In addition to the signs enumerated above, among the most frequently encountered are a high cephalic index, epicanthal folds, fissured tongue, dwarfed stature, small rounded ears, strabismus, white speckling of the iris (Brushfield spots), and lax ligaments. The dermal ridges on the palms and soles have

FIGURE 3. Child with Down's syndrome (mongolism). Note the facial features, the single palmar crease, and the short and incurved little fingers. (Courtesy of Dr. Beale H. Ong, Children's Hospital, Washington, D.C.)

a characteristic configuration, which is often diagnostic. Occasionally, one sees a patient with only a few of these stigmata, looking relatively normal. Many of these have normal or even superior intelligence.

Life expectancy used to be about 12 years. But with the advent of antibiotics, few young patients succumb to infections, and one may contemplate a normal or near normal life expectancy for most patients. Despite numerous therapeutic recommendations, no treatment has proved to be effective.

b. Cat-cry syndrome (*cri du chat*): This aberration consists of a missing part of the fifth chromosome. The affected children are severely retarded and show many stigmata often associated with chromosomal aberrations, such as microcephaly, low set ears, oblique palpebral fissures, hypertelorism, and micrognathia. The characteristic catlike cry—due to laryngeal abnormalities—which gave this syndrome its name, gradually changes and disappears with increasing age.

c. Trisomy 13: This abnormality is also known as holoprosencephaly and is characterized by rudimentary olfactory lobes. The term arhinencephaly was used in the past. Among the clinical signs are low set ears, cleft palate, cleft lip, sloping forehead, single transversal palmar crease, polydactyly, and abnormal dermal patterns. Many associated congenital defects have been described. The patients are mentally retarded and often have minor motor seizures and apneic spells.

d. Trisomy 18: This abnormality occurs with a frequency of 1 in 500 live births. X-ray radiation of the gonads prior to conception has been suggested as the causative factor. The cases reported to date show a preponderance of females (80 per cent). The clinical picture includes mental retardation, low set ears, micrognathia, cardiac anomalies, prominent occiput, hypotonicity at birth followed by hypertonicity, short stature, equinovarus, and overriding fingers and toes. As in other chromosomal aberrations, there is a characteristic dermatoglyphic pattern.

Anomalies of the sex chromosomes. As a group, these disorders are associated with milder forms of mental retardation and sometimes with normal and even superior intelligence.

a. Klinefelter's syndrome: The male patients with this disorder have testicular atrophy evident at puberty and signs of feminization, such as gynecomastia. Their karyotypes usually show an XXY pattern. There is a darkly stained Barr chromatin body in the nuclei of the cells on the nuclear membrane; this is a female nucleus pattern dependent on there being two X chromosomes, one of which is genetically active and the other inactive and constituting the nuclear sex chromatin body, according to the Lyon hypothesis.

Other variants with similar physical characteristics have been detected, mostly among institutionalized mentally retarded. Their sex chromosome pattern shows a wide range of aberrations, such as XXXY, XXXXY, and XYYY. There are frequent mosaics and associations with autosomal trisomies.

The degree of mental retardation in all these patients may vary from mild to severe, but many of them have normal intelligence. The patients are generally cooperative but may develop serious social and body image difficulties, leading sometimes to social withdrawal, serious difficulties in adjustment, especially in adolescence, and paranoid tendencies.

b. Ovarian dysgenesis (*Turner's syndrome*): The main clinical features of this disorder are small stature, webbed neck, and cubitus valgus. The chromosomal pattern is usually XO, and only a minority of the patients are mentally retarded.

A greater preponderance of mental retardation of mild to moderate degree is found among the so-called super females, most of whom have no physical abnormalities, but they do have three X chromosomes, giving them a total of 47. A smaller group exists with four X chromosomes, for a total of 48.

Neuropathological aspects of prenatal developmental anomalies. The exact nature of the damage or malformation of the central nervous system underlying mental retardation is often difficult to assess. The reaction of the immature nervous tissue differs from the reaction of adult tissue to injury and disease, and the telltale signs of previous destruction in the form of an overgrowth of neuroglial and connective tissue are often missing. The effects of endogenous genetic disturbances may be indistinguishable from those of exogenous origin. The remarkable recovery potential of the immature brain may account for the often striking discrepancy between the degree of retardation and the relative paucity of neuropathological finding. Conversely, intellectual function may be normal in the presence of significant brain damage.

The time of the insult to the CNS, the nature of the injurious agent, and the extent of tissue recovery are the decisive factors in determining the ultimate extent and effect of the CNS damage. However, its final form, available to investigation, may not give precise clues as to the time and duration of the injury. In fact, it is often difficult to distinguish between an abrupt arrest of development and a more gradual delay in maturation.

Structural damage may vary a great deal in response to the same noxa. For instance, the effects of German measles on the fetus may range from deafness through microcephaly and hydrocephalus to fetal death. In addition to the stage of embryogenesis at the time of maternal infection, there are still many, largely unexplored, factors responsible for these wide variations.

Present knowledge is still limited as to the etiology of most intrauterine malformations of the brain, the incrimination of x-ray radiation and German measles being the only exceptions. The mechanism of brain damage in the neonatal period is more predictable, with a characteristic response of the brain tissue to ischemia and asphyxia, which produce structural lesions in the cortical and subcortical tissues. The infant in the neonatal period severs his dependence on the maternal circulation and thus becomes vulnerable to toxic substances that were formerly cleared and removed by the maternal circulatory system. This explains the fact that most of the inborn errors of metabolism do not become manifest until the neonatal period, and structural CNS damage may be prevented by early treatment. The postnatal period is also characterized by a rapid myelination marked by the appearance of various disorders of fat metabolism affecting the central nervous system.

Autosomal dominant disorders. These anomalies are determined by single dominant genes of variable expressivity and penetrance and are rare, since many of those afflicted are infertile. The clinical picture varies greatly, and mild forms with minimal signs and only mild mental retardation are often seen. In

addition to cerebral defects, these disorders involve ectodermal, visceral, and skeletal anomalies.

a. Dystrophia myotonica: Wasting and weakness of muscles of the extremities, face, jaw, and neck are the main characteristics of this disorder. Cataracts, alopecia, and testicular atrophy are found in some cases. All symptoms usually appear in young adults and are often accompanied by moderate to severe mental retardation.

b. Epiloia (tuberous sclerosis): This autosomal disorder may manifest itself with great variability, probably due to the irregularity of the abnormal gene or to the influence of additional modifying genes. The skin lesions consist of sebaceous adenomata, red on the face, and brownish white on the rest of the body. Throughout the cerebral cortex in the lateral ventricles and in the cerebellum, multiple nodules are found, of rubber consistency, composed mainly of glial tissue, with some giant undifferentiated nerve cells. In addition, tumors are found in various parts of the body, such as rhabdomyoma of the heart, mixed kidney tumors, hepatic fibrolipoma, and retinal nerve tumors. (See Figure 4.)

The clinical picture is often complicated by systemic manifestations, such as cardiac failure, respiratory disease due to pulmonary cysts, and retinal involvement. The degree of mental retardation may vary from mild to very severe, and other signs and symptoms show similar variability. Of special interest are cases with psychotic symptoms, often with only moderate retardation.

The prognosis varies with the degree and location of the systemic involvement. Mild forms of the disease may occur with only minimal skin involvement or epilepsy. X-ray of the skull may reveal multiple calcification.

FIGURE 4. Sebaceous adenomata on the face in tuberous sclerosis. (Courtesy of Dr. Richmond S. Paine, Children's Hospital, Washington, D.C.)

FIGURE 5. Neurofibromatosis. Note the *café au lait* spots over the trunk. (Courtesy of Dr. Richmond Paine, Children's Hospital, Washington, D. C.)

Treatment is limited to anticonvulsant medication, which is usually effective in controlling the seizures.

c. Neurofibromatosis (von Recklinghausen disease): The main features of this disorder are small brown patches distributed over the entire body along the course of subcutaneous nerves, autonomic nerves, and nerve trunks. Sensory nerves are usually more affected. Astrocytomas, ependymomas, and meningiomas may be found in the brain. The skin manifestation usually begins in childhood and may include large skin polyps and *café au lait* spots over the trunk and extremities (see Figure 5). Acoustic or optic nerve glioma may also occur. In addition to the skin manifestations, the clinical picture includes epilepsy and, in about 10 per cent of cases, mental retardation as well.

Anticonvulsant medication and neurosurgery may sometimes be effective, because of the benign nature of the tumors.

d. Encephalofacial angiomatosis (Sturge-Weber disease): This disorder is believed to be due to an irregularly dominant gene, but the exact mechanism of hereditary transmission is not yet clear. In its classical form, the syndrome includes a facial nevus in the distribution of the fifth cranial nerve, buphthalmos, hemiparesis of the contralateral extremities, convulsions, and mental retardation. The convulsions and mental retardation are due to intracranial angiomata, which often become calcified and may be radiologically demonstrated. Neurosurgical intervention has been attempted but is rarely successful.

e. Retinocerebellar angiomatosis (Hippel-Lindau disease): Familial occurrence of this rare disorder has been reported. The

pathological findings consist of angiomas in the cerebellum and the retina. The clinical picture includes mental retardation and cerebellar signs.

f. Arachnodactyly (Marfan's syndrome): Arachnodactyly is an inheritable disorder, probably transmitted by a single, dominant gene of variable expressivity. It involves changes in many parts of the body, chiefly in the skeletal, cardiovascular, and ocular structures. The patients are tall, have long extremities with long, spider-like fingers and toes, coloboma, bilateral lens dislocation, and cardiac anomalies. The accompanying mental retardation is usually mild.

g. Sjögren's disease: This rare disease is transmitted by a dominant autosomal gene. Its clinical features include mental retardation, congenital cataracts, and ataxia.

h. Congenital ichthyosis: Several variants of this skin disorder have been described. The clinical picture is characterized by generalized scaliness, associated with spastic diplegia or epilepsy in the form of generalized motor seizures. The mental retardation varies from moderate in cases with epilepsy to severe in cases with spastic diplegia.

i. Chondrodystrophy (achondroplasia): This disorder is characterized by very short limbs due to a disturbed ossification of the cartilage. The head is often large, and the accompanying mental retardation is usually mild.

j. Craniosynostosis: This group includes several conditions characterized by premature closure of cranial sutures, skull deformities, and brain damage due to increased intracranial pressure. Allen includes in this group the formerly separate syndrome of Crouzon (craniofacial dysostosis). The etiology of most cases is still unknown, but a dominant mode of inheritance was reported in some instances, with a familial tendency to the same type of anomaly. Since not all the cranial sutures are necessarily involved, the shape of the skull may vary greatly. Its normal growth is inhibited in a direction perpendicular to the obliterated suture line, and compensatory growth takes place in other directions. The degree of brain damage may

depend on the ultimate size rather than shape of the skull, but an associated brain anomaly may exist in some cases. A premature fusion of multiple sutures will result in increased intracranial pressure during the critical first 2 years of rapid brain growth.

The elongated cranium (dolichocephaly) is most common. The broad skull (brachycephaly) represents another variant. Obliteration of all cranial sutures results in a pointed skull (acrocephaly). Several facial and orbital deformities may be associated with various forms of craniosynostosis, such as hypertelorism, shallow orbits resulting in exophthalmos, a beak-shaped nose, choanal atresia, and several others. Syndactyly is often associated with acrocephaly.

The infants may be normal at birth but, during infancy, begin to manifest a variety of signs and symptoms due to increased intracranial pressure: papilledema, optic atrophy, vomiting, and seizures. Mental retardation often follows. The severity of the clinical picture rises in inverse proportion to the time of the fusion. X-rays of the skull may show digital markings due to increased intracranial pressure and calcification of the intercranial sutures. Surgical separation of the cranial bones may be effective if done early, before permanent brain damage occurs.

k. Hypertelorism: This disorder is characterized by a very wide distance between the eyes, which may be seen in several other disorders. Familial occurrence of this disorder indicates a dominant mode of inheritance in most cases, but some cases with a recessive mechanism have been reported.

In addition to the ocular feature, the patients manifest a flat nasal bridge, external strabismus, and sometimes a vertical midline groove in the forehead. The mentality ranges from normal to moderate retardation. Some retarded patients with this anomaly have hyperamino aciduria. Convulsions may occur.

l. Nephrogenic diabetes insipidus: This disorder is usually restricted to males and is counted by some among the sex-linked dominant genetic disorders. The defect lies in the renal tubules and leads to periodic dehydration. Mental retardation and delay in growth are frequent.

Developmental anomalies due to recessive or unknown genetic mechanism

a. Anencephaly: The etiology of this lethal anomaly is unknown, but it is believed by some to be an autosomal recessive disorder. It is one of the most common congenital brain malformations, and its incidence ranges between 0.5 and 3.7 per 1,000. The anencephalic fetus usually succumbs during delivery or shortly thereafter. The pathological findings include an absence of the cranial vault and most of the central nervous system or at least the absence of both cerebral hemispheres.

b. Hydranencephaly: This condition of unknown etiology is characterized by the absence of the cerebral cortex but intact meninges and cranium, the latter filled with clear fluid. The infant may live for several weeks or even a few months and may appear normal at birth. Shortly thereafter, however, he develops convulsions and rigidity of the extremities, and the head enlarges rapidly. Pneumoencephalogram and transillumination of the head are usually diagnostic.

c. Porencephaly: This disorder is characterized by cystic formations in the cerebral hemispheres, communicating sometimes with the ventricular system or subarachnoid space. The defects vary in size and shape, and the clinical picture depends on the amount of remaining functional cortical tissue. The patients who survive early childhood are usually bedridden, have bilateral hemiplegia or tetraplegia, and are either severely or moderately retarded.

d. Microcephaly: Microcephaly is a purely descriptive term, covering a variety of disorders whose main clinical feature is a small, peculiarly shaped head and mental retardation (see Figure 6).

Microcephaly may be found in 20 per cent of the institutionalized mentally retarded population. The etiology varies

FIGURE 6. Infant with microcephaly. (Courtesy of Dr. Richmond S. Paine, Children's Hospital, Washington, D.C.)

FIGURE 8. Setting sun sign in a normal premature infant. (From Paine, R. S. Neurological conditions of the neonate. *Pediat. Clin. N. Amer.*, 8: 578, 1961. Reproduced with the permission of the author and the W. B. Saunders Company.)

greatly and includes a hereditary group, one due to intrauterine influences, and one due to insults in the perinatal or postnatal period.

The hereditary group is relatively uncommon and includes several varieties, all with an autosomal recessive mode of transmission with one exception—that described by Paine, which follows a sex-linked recessive pattern and is associated with generalized hyperamino aciduria. The clinical picture of the hereditary microcephalics varies but generally is milder than in acquired microcephaly. The patient's small head and birdlike face contrasts with an undersized but relatively well developed body. Only a minority in this group have disturbance in motor functions, and they are usually severely retarded. The rest fit into the moderately retarded group.

Microcephaly due to intrauterine influences comprises a far larger group. The etiology includes x-ray radiation during pregnancy, maternal rubella, toxoplasmosis, maternal diabetes and, cytomegalic inclusion body disease. These variants often have severe neurological abnormalities in the motor and sensory area that range from a mild spastic paralysis with general delay in development to a spastic tetraplegia or blindness, associated with profound mental retardation. Convulsions occur in this group with great frequency. The etiology is often indicated by associated pathological findings, characteristic of the causative agent. These include deafness, microphthalmia, cataracts, cardiac anomalies, hepatosplenomegaly, and many others.

In the perinatal and postnatal group the microcephaly is caused by fetal anoxia, episodes of cardiac arrest, or uncontrolled seizures.

The brain in all types of microcephaly is very small and presents a generalized maldevelopment of the cerebral convolutions and disorganization of the cortical structure of varying degrees. Some cases show intracranial calcifications and cortical atrophy.

e. Macrocephaly: The unusually large size of the brain in this disorder is due primarily to the proliferation of the glial tissue in the white matter of the hemispheres. The clinical features include mental retardation, epilepsy, and disturbances of vision.

In agyria and pachygyria, the convolutions of the brain are

absent or maldeveloped. Both anomalies are associated with a severe degree of mental retardation.

f. Hydrocephalus: This name covers a number of conditions having in common an increase in the cerebrospinal fluid, resulting in the enlargement of the head or the ventricles. This group of disorders is listed here because one of its variants, usually due to atresia of the aqueduct, has a sex-linked recessive mode of inheritance. Many cases, however, are due to developmental malformations of undetermined origin, including atresias of the foramina of Magendie and Luschke and of the aqueduct Sylvii, and Arnold-Chiari malformation. The latter is a medullary-cerebellar anomaly, often associated with spina bifida, meningocele, displacement of the medulla into the cervical canal, and occasionally cortical defects. The cases of hydrocephalus that follow viral, bacterial, or aseptic meningitis are due to obstructing fibrosis of the arachnoid tissue.

The abnormality is seldom noted until the 2nd or 3rd month of life, when a rapid enlargement of the head circumference makes its first clinical appearance. The fontanelle becomes tense, and the cranial sutures widen. The head enlarges in all directions. Symptoms of increased intracranial pressure, such as vomiting, papilledema, and rigidity, soon follow. Progressive hydrocephalus leads to dilation of the lateral ventricles, cortical atrophy, and many severe neurological symptoms; it often ends in complete mental and physical deterioration. In milder cases the condition may become spontaneously arrested, and the afflicted children may be only mildly retarded and even have normal intelligence in some cases (see Figures 7 and 8).

g. Agenesis of the corpus callosum: This rare disorder is characterized by the partial or total absence of the great commissure connecting the cerebral hemispheres. This anomaly may be associated with other cerebral defects, such as porencephaly, microgyria, and hydrocephalus. The etiology is unclear, but some cases are believed to be genetically determined.

The clinical picture varies with the extent of associated brain anomalies. Mental retardation of varying severity and major, minor, or focal seizures are common. Other neurological disturbances may occur, such as spastic diplegia, hemiparesis, athetosis, and optic atrophy. The pneumoencephalogram

shows several characteristic features, of which the marked separation of the lateral ventricles is one.

h. **Congenital mental retardation:** This large group includes a great variety of mentally retarded children who do not fit into any known clinical category. In addition to mental retardation already evident in early infancy, they may display a variety of nonspecific neurological signs, but many are asymptomatic. Autopsies may reveal many neurological changes, which do not follow a regular pattern.

The etiology of most of these cases is obscure and probably includes genetic influences, developmental arrest, and toxic infectious agents. It is to be hoped that, with increased knowledge, this "wastebasket" group will rapidly dwindle. The last 2 decades witnessed a good start in this direction.

i. **Laurence-Moon-Biedl syndrome:** This disorder usually follows an autosomal recessive mode of transmission, but some sex-linked tendency may be suspected from a higher frequency in males.

The main features include mental retardation, retinitis pigmentosa, obesity, hypogenitalism, polydactyly, and deaf-mutism.

Maternal infections during pregnancy

Syphilis. Syphilis in pregnant women used to be a major cause of a variety of neuropathological changes in their offspring, including mental retardation. Today the incidence of syphilitic complications of pregnancy fluctuates with the incidence of syphilis in the general population. Some recent alarming statistics from several major cities in the United States indicate that there is still no room for complacency.

Rubella (German measles). This disease has replaced syphilis as the major cause of congenital malformation and mental retardation due to maternal infection. The children of affected mothers may present a number of abnormalities, including congenital heart disease, mental retardation, cataracts, deafness, microcephaly, and microphthalmia. Timing is crucial, since the extent and frequency of complications are in inverse proportion to the duration of pregnancy at the time of maternal infection. When mothers are infected in the 1st trimester of pregnancy, 10 to 15 per cent of the children will be affected, and the incidence rises to almost 50 per cent when the infection occurs in the 1st month of pregnancy. The situation is often complicated by subclinical forms of maternal infection, which often go undetected.

Other diseases. Brain damage due to toxoplasmosis and cytomegalic inclusion body disease transmitted from the pregnant mother to the fetus is another universally recognized but relatively rare complication of pregnancy that often results in mental retardation and a variety of brain malformations. Damage to the fetus from maternal hepatitis has also been reported.

The role of other maternal infections during pregnancy—such as influenza, cold viruses, pneumonia, and urinary tract infections—in the etiology of mental retardation is at present under extensive investigation. The results are as yet inconclusive.

Complications of pregnancy. Toxemia of pregnancy and uncontrolled maternal diabetes present hazards to the fetus and may sometimes result in mental retardation. Maternal malnutrition during pregnancy often results in prematurity and other obstetrical complications. Vaginal hemorrhage, placenta previa, and premature separation of the placenta may be damaging to the fetal brain by causing anoxia. The same may be said about the prolapse of the cord.

The potential teratogenic effect of pharmacological agents administered during pregnancy was widely

publicized following the thalidomide tragedy. So far, with the exception of metabolites used in cancer chemotherapy, no usual dosages of drugs are known to damage the central nervous system of the fetus, but caution and restraint in prescribing drugs to pregnant women is certainly indicated.

Perinatal factors

Prematurity. Many studies point to prematurity as a major cause of disorders of the CNS that are often associated with mental retardation. Paradoxically, improvements in obstetrical techniques result in a higher survival rate of low birth weight infants, who are likely to be damaged, since there is an inverse relationship between the degree of damage and the weight at birth. Similarly, there is now a higher survival rate of brain-damaged children who are salvaged by improved obstetrical and pediatric methods.

Prematurity may result in intellectual deficits, sensory and motor handicaps, convulsive disorders, and learning and emotional difficulties. Only a minority of infants weighing less than 1,500 gm. (3 lb. 4 oz.) escape these sequelae.

Prematurity is more prevalent in low socioeconomic segments of the population. Its causes are many and include inadequate prenatal care, with resulting obstetrical complications, such as toxemia and pre-toxemic states; multiple births and illegitimate pregnancy; poor maternal nutritional status; mothers' smoking habits; and urinary infections.

Birth injury. This broad term covers all types of brain damage resulting from complications of labor or delivery. Some are due to mechanical trauma, others are due to anoxia, but most cases result from an interplay between these two factors.

Traumatic cerebral insults. These include cephalopelvic disproportion, breech delivery, abnormal presentations necessitating the use of mid-forceps and high forceps, and prolonged labor. They may result in subarachnoid and intraventricular hemorrhage, the latter occurring chiefly in prematures.

Anoxic factors. Anoxemia may occur before, during, and after delivery. Cesarean section and some of the obstetrical complications mentioned under prenatal factors may result in fetal anoxia due to a fall in systemic blood pressure. Changes in fetal heart rate, especially bradycardia, are the best indicators of fetal distress. Respiratory difficulties may be caused by mechanical factors, such as intratracheal mucus plug, or by fetal respiratory depression due to analgesic and anesthetic drugs administered to the mother during labor.

The neuropathological changes following birth injuries are varied and may be found in the cortex, the cerebellum, and the basal ganglia. The most common sequelae include destruction of cortical tissue, with resulting sclerosis, gliosis of white matter, calcification, and cystic cavitation.

Kernicterus. This name refers to yellow staining

of the basal ganglia, cerebellum, and brain stem, resulting frequently in cerebral palsy, mental retardation, and hearing deficit. The pigmentation is caused by the excess of nonconjugated (indirect) bilirubin, which is neurotropic, while the conjugated (direct) bilirubin does not enter the nerve cell, for still unexplained reasons. The conversion of indirect to direct bilirubin is effected through conjugation with glucuronic acid, mediated by the enzyme glucuronyl transferase.

Kernicterus follows some cases of neonatal jaundice, because of the low enzymatic activity of the newborn, especially the premature infant. It seldom develops unless the level of indirect bilirubin in the blood exceeds 20 mg. per 100 ml. The jaundice usually begins shortly after birth and becomes progressively more extensive, leading to hepatosplenomegaly, apathy, and neurological signs such as rigidity, inactivity, sometimes flaccidity, a high-pitched or feeble cry, poor Moro's reflex, downward deviation of the eyes, and poor feeding. These signs usually appear on the 3rd to 5th day after birth.

Erythroblastosis fetalis. This is the most common cause of nonphysiological jaundice and is due to mother-child incompatibility regarding the Rh factor, A or B, or (rarely) Kell, Kidd, and Duffy factors in the blood. The resulting breakdown of the infant red cells causes bilirubinemia and anemia. Stillbirth due to a generalized edema, hydrops fetalis, occurs in some cases.

Other causes. Neonatal sepsis, glucose 6-phosphate dehydrogenase deficiency, prematurity, administration of vitamin K, sulfonamides, salicylates, some antibiotics, and caffeine and sodium benzoate may all result in indirect hyperbilirubinemia. Exchange transfusion represents the most effective treatment and should be done repeatedly, if necessary, to keep the indirect bilirubin level in the blood below the critical 20 mg. per 100 ml. level. Exchange transfusion carries some risk to the infant, and the risk is greater in prematures. More judicious use of vitamin K, sulfonamides, antibiotics, and salicylates in newborn infants is definitely indicated.

Postnatal factors. Advances in antibiotic therapy that permit a higher survival rate of children with infections of the CNS have as a corollary a high frequency of neurological sequelae in the survivors. The extent of the damage varies from mild learning or behavioral disorders to severe dementia, and it depends on several factors, such as the severity of the infection, the nature of the microorganism, and the age of the child.

Purulent meningitis. This may be successfully treated in most cases if recognized early, but drug-resistant cases may lead to extensive destruction of brain tissue. Subdural effusion is one of many complications that may cause brain damage if unrecognized and untreated. Meningitis caused by pneumococcus usually results in the highest frequency of brain damage, and meningococcus meningitis is the most benign. Tuberculous meningitis also leaves many survivors with extensive chronic encephalopathy.

Viral meningoencephalitis. This group includes poliomyelitis, ECHO virus, Coxsackie virus, herpes simplex, and arthropod-borne encephalitis, still prevalent in some geographic areas. The clinical course varies a great deal, as does the extent of damage to the CNS. Infants run the greatest risk of

permanent sequelae, but recovery in even very severe cases is spectacular at times.

Aseptic meningoencephalitis. Aseptic meningitis is seen with the Coxsackie and ECHO viruses, mumps, and herpes simplex. It is usually benign and without residue. An exception is that, due to the herpes-simplex virus in the newborn period, which produces encephalohepatomyocarditis with a high fatality rate and usually damaged survivors.

Parainfectious encephalomyelitis involves small areas of perivenous demyelination but has a lesser inflammatory reaction and does not involve a demonstrable direct viral invasion of the central nervous system.

There is a major possibility of preventing many of these complications by immunization against measles and by performance of smallpox vaccination at the age when the statistical likelihood of involvement of the central nervous system is least—between 1 and 2 years of age. Steroid therapy may be of value in treatment, but this is still uncertain. The sequelae of these complications may include sensory and motor disabilities, convulsive disorders, and mental retardation.

Lead poisoning. This condition, which frequently leads to chronic encephalopathy and mental retardation, is still quite common in large cities among the disadvantaged population. Old houses in numerous slums, coated with lead-containing paints, and a faulty mother-child interaction, characteristic of children with pica, result in the still appallingly high number of permanently damaged children. Treatment with chelating agents such as Versene, followed by removal of the source of lead, may prevent residual damage.

Many other toxic substances accidentally ingested by infants and children may cause brain damage and are seen most frequently in chaotic households where children lack supervision and mothers are overwhelmed by their family obligations.

Another type of toxic influence in the postnatal period is presented by metabolic disorders, previously discussed, which often do not produce mental retardation and neurological disorders until after birth.

Traumas. Head injuries in children seldom produce serious brain damage and mental retardation.

Convulsive disorders. Although most convulsive disorders probably result from prenatal or perinatal influences, they make their appearance in the postnatal period, and their etiology often remains unclear. The underlying pathology of the central nervous system is usually responsible for the epilepsy and the associated mental retardation. This association is seen with great frequency among the moderately and, especially, the severely retarded. It is estimated that as many as 20 to 25 per cent of the population in institutions for the mentally retarded have epilepsy. Failure to treat status epilepticus promptly and vigorously may also lead to progressive mental deterioration. Major motor and mixed or unclassifiable seizures account for the majority of convulsive disorders among the mentally retarded.

Infantile spasms. This condition, also known as hypsarrhythmia or massive myoclonic seizures of infancy, usually affects infants between 3 and 12 months of age. The illness is characterized by brief lapses of consciousness with abrupt symmetrical flexion of the head, trunk, or extremities. The EEG is characterized by grossly disorganized slow background frequencies associated with diffuse random high voltage spike activity.

The condition leads to progressive mental deterioration, and mental retardation has been reported in close to 90 per cent of the cases. The etiology is unclear and probably includes a variety of mechanical (birth) and biochemical insults to the central nervous system. The majority of cases occur suddenly and for no apparent reason in a previously normal child.

Recent reports about the beneficial results of ACTH are promising, although they must still await the verdict of time.

Febrile convulsions. Convulsions accompanying nonspecific febrile illness in infancy are harmless in most cases. Sometimes,

however, they are a forerunner of an epileptic disorder. Rare cases have been reported of mental retardation following such convulsions.

Cerebral palsy. The estimates of intelligence of patients with cerebral palsy vary greatly, but all agree on the high incidence of mental retardation in this group. This incidence seems related to the type of cerebral palsy. The patients in the spastic tetraplegic group are most affected, and less than 15 per cent possess normal intelligence. In the hemiplegic category, the patients who acquired the handicap postnatally, especially in infancy, do worse than patients with hemiplegia due to prenatal or perinatal causes.

The incidence of mental defect in the hemiplegic group ranges between 40 and 50 per cent. Of the remainder, about half are of borderline intelligence.

Patients with the extrapyramidal type of cerebral palsy are more intelligent than the spastic group, and as many as 50 per cent may fall in the normal or superior range of intelligence. The intelligence of patients in the extrapyramidal category is sometimes underestimated due to hearing and speech disorders frequent in this group.

Heller's disease. This condition was first described by Heller, and, since the time of its original description, there has been a heated controversy. The lines are sharply drawn between those people who accept it as a legitimate disease entity and those who regard it as a meaningless label covering a variety of neuropathological and psychotic conditions. In his original report, Heller described children who developed normally in all respects until their 3rd or 4th year, when, without any apparent reason, they began to show signs of progressive deterioration. The changes began with restlessness, stereotyped and anxious behavior, and loss of already learned speech, and led to complete dementia. The children retained an intelligent facial expression and had no localizing neurological signs.

Since the original description by Heller, a number of clinical reports from various countries have appeared in the literature, and some give details of neuropathological findings that include nonspecific structural alterations in various areas of the brain. These authors prefer to consider Heller's disease as a *syndrome* of progressive mental deterioration beginning in early childhood and due to a variety of yet undetermined insults to the central nervous system. These may include traumatic, infectious, and biochemical influences occurring postnatally, or they may be genetically determined. Further systematic research may break down this global concept into several separate clinical units.

Sociocultural factors. It was mentioned previously that the overwhelming majority of the mentally retarded in the United States come from the lowest socioeconomic group. These are the indigent, dependent, helpless, hopeless, and often illiterate members of racial minorities, inhabitants of backward rural communities and urban slums. Exact statistics are not available, but the estimates of the frequency of mental retardation in this segment of the population range between 10 and 30 per cent, as contrasted with about 3 per cent in the total population. Many factors contribute to this sad picture, which was brought into sharp focus by the report of the President's Panel on Mental Retardation.

Medical problems. The medical problems of the disadvantaged group are many and are often related to the problem of mental retardation. The prospective mother is frequently malnourished and shorter than her more fortunate suburbanite sister. She is likely to have either poor, little, or no prenatal care. Con-

sequently, pretoxemic and toxemic states are seen in the disadvantaged group in much higher proportions. The diet often lacks the necessary minimum of vitamins, iron, and minerals. Maternal infections during pregnancy, including lues, are treated with delay or not at all. Many of these factors may result in grave hazards to the fetus. Infant mortality is higher than usual, and so is the rate of prematurity. Diabetes in the mother is often uncontrolled. Each of the many fetal risks may result in brain damage and mental retardation. As demonstrated by Pasamanick and others, this group's contribution to the continuum of reproductive casualty is extremely high.

The baby continues to be exposed to many health hazards after birth. He may never have regular postnatal care, including routine checkups and immunizations, and his contacts with medicine may be limited to occasional emergency visits to the hospital. As a result, he is more likely to have serious bacterial and viral infections. He is treated relatively late in the course of illness for conditions such as meningitis or dehydration, often when permanent damage has already been done. The same may be said of conditions potentially amenable to surgical treatment that may go unrecognized for a long time.

Where there is mild brain damage that could be expected to be compensated for by appropriate handling and experience, such damage often persists because of understimulation or overstimulation.

The infant's nutrition is often inadequate and consists chiefly of milk, resulting in frequent iron deficiency anemia. Actual starvation is not frequent in the United States, but there are many families with little income and many children, whose members subsist on a substandard diet. Several studies in Central and South America indicate that chronic protein depletion in infants and young children may produce irreversible mental retardation of mild to moderate degree.

As the child grows older, other health hazards are added, such as pica, which often ends in lead poisoning, encephalopathy, and mental retardation. Mothers of children with pica are often immature, overwhelmed by their family duties, and unavailable to their children. Old paint used on the walls of dilapidated slum houses provides a steady supply of lead for children who eat plaster. The frequency of the battered-child syndrome, burns, serious accidents, and ingestion of toxic substances, with inherent risks to the central nervous system, is disproportionately high in this group.

Emotional and social problems. These problems of the disadvantaged group have been widely discussed recently. There is always danger in describing a heterogeneous population. It is easy to oversimplify matters, to generalize, to think in stereotypes. The majority of disadvantaged families are upwardly mobile, have sound ambitions for their children, and have not given up the struggle to help themselves.

This discussion concentrates on the lowest 15 to 20 per cent of this group, which produces the majority of the culturally determined retardation. Family cohesion is often missing, the children are often illegitimate and reared by a variety of caretakers in addition to the mother, who is frequently working. These polymatric families often lack a father, and sometimes a grandmother assumes the role of head of the household. More often the roles of the family members are ill defined, resulting in a chaotic, disorganized household, where things are not planned but just happen. In such an environment, the dependency needs of the growing infant, toddler, and young child may not be met, and he is forced to fend for himself long before he is ready. Having many caretakers—grandmothers, aunts, neighbors, a 2-year-old sister—may result in distorted pictures of human attachments and object relations, so vital to future personality development and social interaction. Because of lack of proper limits and because of the behavior standards they are exposed to, the children may identify themselves with patterns of poor impulse control and are apt to act out rather than sublimate their aggressive and sexual drives. As a result of living in a world that seems hostile, without encouragement and praise, the child's self concept, including his body image, may be faulty. The fatalistic, hopeless attitudes of the slum environment can stifle initiative and motivation. The defenses necessary to allow the individual child to learn how to survive in this environment, where violence is not unusual, may also interfere with intellectual progress, particularly by emphasizing the need to deal with concrete realities, often ending in lack of flexibility in thinking.

Environmental deprivation. Recent research in sensory deprivation and studies of children in institutions have provided the main impetus for the study of the role of environmental factors in the etiology of sociocultural mental retardation. Appropriate sensory stimulation of the young infant to facilitate his intellectual development is being widely explored for utilization in preventive approaches. There are still many unanswered and controversial questions in this area, but there are already many areas of agreement.

The importance of a stable, focal care-taking person in the intellectual and emotional development of an infant and toddler is undisputed. Young children need routine and predictability in their environment as well as variety, offered in proper balance. For example, a range of verbal stimulations that begins to elicit response from the infant by the age of 2 months is crucial in the development of language, the foundation of abstract thinking.

The disadvantaged socioeconomic environment confronts a growing child with several hazards to his intellectual development. The level of sensory stimulation may be too low or too high, or it may vacillate between the two extremes, with many possible out-

comes, including the passive, unresponsive, or highly irritable child. Life may be drab and monotonous, with a paucity of new people, new toys, and new experiences, or it may be very chaotic and violent, devoid of any regularity, with new people coming and going without a predictable pattern. The available verbal stimulation is frequently deficient, resulting in a meager vocabulary, poor sentence structure, and concrete reasoning—a poor basis for a school learning experience. Nonverbal language, particularly body language, is often the chief communication medium, which deprives the child of more complex verbal skills, hindering his transition to more abstract thinking. The care-taking figure, even if regularly available, may at best attempt to satisfy the child's physical wants but will have little or no opportunity for playing with the child or providing him with new pleasurable experiences.

It is particularly in the institutional setting for infants and young children that the greatest hazards exist for environmental deprivation. There, preventive measures should be applied. Hospital nurseries, too, must provide a stimulating environment for babies.

Familial mental retardation. It was the usual practice in the past to begin the classification of the mentally retarded with the large category of familial retardation, also known as garden variety, physiological retardation, or "poor protoplasm." It is currently fashionable to dismiss this group as an artifact rather than a medical or biological entity. The main difficulty in resolving these opposing viewpoints lies in the lack of objective, observable, genetically determined characteristics of this group, which leaves the field open for speculation.

There is fairly wide agreement as to some characteristics of children in this category. Its members comprise about 75 per cent of all the mentally retarded in this country and usually come from the lowest socioeconomic group. In addition to being mentally retarded, they are the chief contributors to the ranks of juvenile delinquents, the jobless, and the mentally ill. They have no neurological signs, neuropathological abnormalities, chromosomal or known biochemical characteristics to distinguish them from the rest of the population. Finally, in borderline to mild retardation there is usually a consistency in I.Q. among members of the same family.

It may be assumed that intelligence, or rather its multiple components, are in part genetically determined. The distribution of measurable intelligence in the general population may be represented by a bell-shaped Gaussian curve skewed to the left, since there are far more people falling in the below average category than those in the above average or superior range. But the statistical speculations cited in support of the hereditary nature of intelligence are subject to considerable distortions. Nobody will dispute the high correlation between the I.Q. of

members of the same family. This is, however, complicated by the usually equal exposure of all the family members to identical or similar environmental influences.

The studies of Skeels on the remarkable effects of a stimulating environment in enhancing the intellectual level of retarded institutionalized children and recent experiences in the Head Start program indicate that, with appropriate experience, gains can be made by children from deprived families. Even more startling were the experiences during World War II with illiterate recruits, who were taught to read and write in crash programs of only 3 months' duration.

Psychiatric factors

Personality development in mentally retarded children. Differences in the degree of intellectual functioning in the mentally retarded are compounded by the divergence of etiological factors, ranging from clearly demonstrable brain damage—occurring in all phases of prenatal and postnatal development from a multitude of causes—to emotional and cultural deprivation. The resulting extreme heterogeneity of the mentally retarded group is probably responsible for the often conflicting and confusing views about the personality development and frequency of psychopathology of its members. What contributes to the existing confusion in this field is the paucity of well conducted studies and surveys that use similar standardized methods of investigation. Most assumptions are often based on studies using residents in state institutions or patients in psychiatric clinics and hospitals. No wonder the views on the personality development of the mentally retarded range widely from the assumption of little or no difference from the normal population in the frequency of emotional disturbance to the contrasting opinion that assigns to the mentally retarded a very high risk of psychotic illness—up to 40 per cent in some studies.

Most people agree that there is, at present, no solid objective body of evidence to support a definitive opinion in this matter, and only well detailed, well designed studies of the course of personality development in well defined uniform groups of mentally retarded will provide the answer in the future. Fortunately, similar studies of normal infants and children are being conducted with increasing frequency. They contribute very useful clues to the field of mental retardation, in addition to providing good research models. Until the results of such systematic studies become available, clinical experience, coupled with cautious speculation, will have to be relied on.

Many borderline, mildly retarded, and even severely retarded persons are capable of having as normal a personality development as those with normal intelligence. Given an accepting and adequately stimulating family environment and appropriate educational and vocational training facilities, the majority of retarded children can develop good social and vocational adjustment and capacity for appro-

priate interpersonal interactions and attachments. However, in the process, they face hazards along the way that exceed the ones facing the normal population. Such hazards seem to increase in direct proportion to the degree of retardation.

Emotional vulnerability

Factors within the child. Modern research in child development stresses the degree of intellectual functioning as a factor of overriding importance in the timetable but not as the essence of the child's successful negotiation of progressive phases of emotional maturation. To give one example: most people agree on the fundamental role of early attachments in infancy, manifesting themselves in recognition and preferential treatment of the mother by the infant (about 4 to 6 months) and in the phenomenon of separation anxiety and fear of strangers (about 6 to 8 months). The infant's recognition of his mother as an entity, separate from himself and clearly distinguishable from others, is an intellectual process that precedes or parallels its affective counterpart. This process of self-differentiation depends, in turn, on intact sensory and perceptual mechanisms, memory, and the ability to organize bits and pieces of experience into a meaningful whole. The infant's failure or delay in the recognition of his mother, for whatever reason, will delay—if severe, it may even preclude—the development of these vital early attachments, thus slowing down and disrupting the timetable of emotional development. One such distortion is the longer duration and greater intensity of the child's dependency period, requiring a delay in developing independence of thought and action. It is particularly important to insure proper resolution of the dependency needs. If they are not properly solved, the child can remain preoccupied with having these needs met throughout its life.

The phase of negativism often starts later in infancy in the retarded and lasts longer than usual, which may interfere with the attainment of autonomy and mastery. The child's responsiveness to people in his environment is often reduced, because of perceptual difficulties and lack of alertness. This, in addition to delay or failure in the mastery of spoken language, interferes with the intricate problems of interpersonal communication, causing a breakdown in the reciprocal exchange of meaningful messages between the child and his environment.

The mentally retarded child often has difficulties on a constitutional basis in handling anxiety and frustration, postponing gratification, handling disappointments, and accepting substitutes. This weakens his emotional resilience and lengthens the period of recovery from an emotional crisis, however small. As the child grows older, his lessened adaptability interferes with the general processes of socialization, which requires cooperation, compromise, and a capacity to give.

The retarded child's self-image, closely related to

his self-acceptance, is often unfavorable, due to his frequent frustrations, failures, mistakes, and distortions in body image.

Play is of crucial importance in the development of a healthy personality. It permits experimentation and the finding of solutions to problems, represents a medium of expression of feelings and ideas, and provides a model for social interactions. The mentally retarded child may lack originality in his play. He may lean toward repetition and stereotype, particularly if there are organic bases for his difficulty. Such children use a minimum of toys and are often unable to play in larger groups or imitate play without help. All this potentially deprives them of yet another vehicle of emotional growth, unless programs are set up to help overcome these handicaps.

In spite of the hazards, it is possible for the vast majority of the retarded to develop personality patterns as normal as compatible with their level of mental functioning. Developmental stages must be properly handled. To function as an individual, a child needs self-help skills and the motivation to use them. To function in society, he needs adequate control over impulses, a sense of responsibility, a good conscience, a reciprocal interest in and participation with others, and habit and character patterns (especially work patterns) that allow for productivity, even though at a limited level.

Since the most important components of personality development are evolved in the first 5 years of life, it is essential to provide the optimal setting and conditions in which this can take place. Most often this is in the home, if the presence of the retarded child is not decompensating for the family.

The role of the family. The role of the mother and other family members in the personality development of a young child is crucial. The parent-child interaction passes through several predictable stages, leading from a very close mother-child union to a gradual loosening of the emotional ties. Usually, the early closeness between mother and child is promoted by the mother's feeling of pride and acceptance and is continually reinforced by the child's predictable responses, such as smiling, cooing, cuddling, and playfulness. Delay in such responses and knowledge of the child's mental retardation often induce parental inner turmoil, grief, a sense of disappointment, shattered hopes, and sometimes feelings of guilt and failure. These feelings, if unresolved, make it difficult for many parents to accept the child, to be proud of him, and to give him affection and recognition.

Ignorance of the fact that the child is mentally retarded is equally hazardous, since parental expectation of normal behavior may be frustrated, leading to tension, confusion, and often estrangement between parent and child. The parents sometimes respond by vacillating between denial, overprotection, infantilization, and overt or covert rejection. The resulting tensions and conflicts may present definite handicaps in the emotional development of the growing child.

Where there are brighter siblings, the inability to compete can be traumatic for the retarded child.

The influence of the community. The community may affect the personality development of the retarded child directly and indirectly. To begin with, the prevailing general attitudes toward mental retardation will profoundly influence the parents' reaction to having a retarded child. The more technologically advanced, sophisticated communities, which put a premium on education and intellectual achievement, have been less accepting and tolerant than the more primitive, underdeveloped ones.

As the child grows older and his social world widens, he comes to depend more on his peers for emotional support and stimulation. His acceptance by other children in the neighborhood, on the playground, and in school will largely depend on the personal attitudes, tolerance, and compassion of their parents. The retarded child, because of his inability to compete, is frequently excluded from neighborhood groups, leading to further frustration and feelings of inadequacy.

The various hazards to normal personality development in the mentally retarded make it difficult, but not necessarily impossible, to achieve normal adjustment. The intellectual capacity plays an important but not deciding role in this process, and it would be a fallacy to equate the level of emotional maturity with mental age. An adolescent mongoloid with a mental age of 4 or 5 years can be trained to perform a set of simple tasks, permitting him to hold a regular job in a supervised setting, which would hardly be expected from a normal 4- or 5-year-old child. The recent visibility given mental retardation tends to create a more enlightened community with more special services and facilities for the retarded, which in turn preserves and enhances their acceptance of themselves.

Maternal deprivation. The undisputed risks that maternal deprivation present to the emotional and intellectual development of a normal child are certainly far greater in a mentally retarded one. The retarded child needs more than the usual amount of mothering, affection, and stimulation. Denial of these results in an often irretrievable loss of whatever inner resources the child possesses. This matter is of particular importance in the problem of early institutionalization.

A more subtle form of maternal deprivation may result from the child's inability to respond to normal mothering because of sensory or perceptual difficulties. The mother's depression, self-preoccupation, or rejection may lead her to neglect the child's emotional needs.

The impact of retarded children on the family. The parents of retarded children represent the total spectrum of human personality variations, and yet there is often a tendency to treat them as a homogeneous group, beset by overwhelming feelings of guilt, anxiety, hostility, and insecurity. There is

no doubt that many parents respond to having a retarded child with some degree of emotional disorganization, but the intensity and quality of their reactions vary greatly. Most of them experience considerable tension and anguish at the time of initial diagnosis, causing a weakening of the habitual defense system and a temporary breakdown of adjustment patterns. Most studies of families with mentally retarded children indicate that the period immediately following the diagnosis is extremely crucial and may have a deciding influence on the parents' handling of the child in the future.

The ultimate impact of the retarded child on the family depends on several factors, such as the degree of retardation, personality development and life adjustment of each parent preceding the arrival of the retarded child, the degree of their professional and social success, the adequacy of the marital adjustment, other children in the family and their intellectual progress, and the parental socioeconomic status. Reasonably well adjusted parents with a positive self-image are usually able to absorb the retarded child without upsetting the family balance or jeopardizing the well-being of other family members. A marriage based on mutual support and free communication and the presence of other normal children helps cushion the blow to the parents' self-esteem.

If, however, the parents are emotionally immature and beset by neurotic conflicts, the arrival of a defective child may precipitate a crisis that sometimes leads to family breakdown. The difficulty of managing a retarded child may contribute to this, particularly if management is complicated by hyperactivity, excessive irritability, or other distressing and hard to control manifestations. As a result, the child may be cast in the role of the family scapegoat, destined to drain off family tensions. In such cases, the removal of the child to an institution is often followed by an increase of marital tensions and sometimes by divorce or separation.

The social life of these families frequently becomes limited, leading to a feeling of isolation. The siblings' acceptance of the retarded child depends largely on parental attitudes and gratification of their own dependency needs.

The degree of family turmoil rises in direct proportion to the parents' social status. In this regard, the disadvantaged members of society fare better than the privileged ones.

The predominant defenses of the family may help or hinder their adjustment to the presence and handling of their retarded child. Denial, which may frustrate the physicians involved, may also allow the family to work usefully with the child. The danger is in overprotection and unrealistic pressure on the child for achievement. Projection, with the parents concentrating on blaming others for the child's situation, can lead to losing sight of the child's needs. Displacement can be useful if properly directed, such

as involvement of the parents in community action on behalf of the retarded. Withdrawal can be destructive if it leads to the whole family's isolating itself and hiding from the rest of the world or concentrating all its investment in the retarded child to the neglect of the other children in the family.

The role of the physician. An informed and interested physician may play a pivotal role in preventing family tensions. An effective intervention on his part includes clarification, support, and reassurance. Bluntness, disinterest, or lack of caution in prognostication only adds insult to injury. The physician's empathy and flexibility help bring the parents' feelings and attitudes to the surface. Patience and flexibility are of particular importance in dealing with parents from low socioeconomic strata. Paying attention to their difficulties in verbalizations and to cultural and ethnic variations in attitudes toward mental retardation greatly increases the physician's effectiveness.

An extensive psychiatric intervention is superfluous for most parents but many profit greatly from counseling by an experienced social worker, and some may need psychiatric treatment. Group therapy for parents of retarded children has also been useful. Above all, the physician should move to relieve the parents' helplessness in the face of the diagnosis of retardation. He needs to give them appropriate things to do, especially in the area of helping the child be as normal as possible in personality and adjustment.

Psychological factors

The nature and development of intelligence. The problem of the nature and determinants of intelligence has baffled people from time immemorial. The controversy continues unabated in our century and has assumed renewed significance with the current interest in mental retardation. It is generally agreed that intelligence represents a man's problem-solving capacities, his adaptability to new situations, his ability to form concepts and to profit from experience. Thus, intelligence may be viewed not as static but rather as forever changing according to the individual's life circumstances.

The difficulty in even defining intelligence in a generally acceptable way may explain in part the never ending controversy about the causative factors in the development of intelligence. In the early part of this century, the lines were sharply drawn between the proponents of the theory of fixed and genetically predetermined intelligence and those who considered environmental factors the most decisive ones. This nature versus nurture controversy was perpetuated by many developments and discoveries, providing support for both factions. Mention can be made of the rapid advances in genetics and increased knowledge of the cell processes, the conceptual model for brain activity provided by information theory and cybernetics, studies of identical twins reared in dissimilar

environments, the recognition of the relevance of obstetrical complications to the functioning of an individual, and the interest in maternal and cultural deprivation.

Today there is a movement away from the extreme positions and a gravitation toward the center. Thus, intelligence is most commonly viewed as resulting from interaction between biological and sociocultural factors. The former include genetic characteristics, prenatal and perinatal factors, favorable and unfavorable influences. The sociocultural factors are experiential and operate on the psychological level. Mental retardation often results from disturbances in all these areas: a genetically vulnerable individual may suffer obstetrical complications and be exposed to a culturally deprived environment. Such cases present a challenge to the most skillful diagnostician. To quote Pasamanick: "The biological determinants serve primarily to establish physiological limits and the floor of potential in the organism. The sociocultural factors are like the soil in which the plant is nurtured. By enrichment or impoverishment, human intellectual potential can be made to blossom or to wither, to achieve its limits or to *fall far short of them.*"

Such a general description of intelligence fits many current theoretical approaches. There is disagreement, however, as to the best methods of tapping or measuring intelligence. The several intelligence tests in common use, which assign to an individual a numerically expressed intelligence quotient (I.Q.), are very useful in predicting school performance. They are, however, less reliable in predicting future social adjustment and problem-solving ability. In addition, the test scores may be lowered by abnormal character traits, overwhelming anxiety, distractibility, and many other factors.

In the past, reliance on the I.Q. often led to keeping a child back in school, since the score was believed to be immutable. The studies of Bayley and others convincingly proved the fallacy of this assumption. There is also a growing realization that intelligence, seen as a sum total of all intellectual processes, is inadequately reflected in the conventional tests. The variety of these processes is far greater than had been thought previously.

The majority of the mentally retarded come from the low socioeconomic segment of society, and their intellectual potential is inadequately measured by the culturally biased conventional tests. There have been several attempts to devise culture-free tests, none of which have gained general acceptance as yet.

The work of Piaget and of the Pavlovian psychologists suggests a possible solution. They place the emphasis on the *nature* of the thinking process rather than on the performance during a defined test period, which may fail to demonstrate the individual's actual intelligence potential.

Some basic defects in cognitive development.

There is general agreement about the reduced ability of the mental retardate to learn, to acquire knowledge at the same rate and in the same quantity as normal children. The differences are small in the simple forms of learning, but the gap widens in direct proportion to the complexity of the learning process. The many existing theories that attempt to define and analyze in detail the process of cognition have been related with varying success to the learning deficits of the mentally retarded.

The difficulty of directing attention to relevant cues has been recently stressed. Short term retention seems deficient in the mentally retarded, but long term retention is not disturbed. This may partially explain the fact that the retarded individual does not profit from a previous single learning experience as much as a normal child with a comparable mental age. The retarded person requires much more repetition and practice.

The sensory and perceptual handicaps found in many of the mentally retarded may significantly contribute to their learning difficulties. Where such defects exist, their responsiveness to various stimuli of normal intensity and duration differs from that of the normal child, making learning difficult without appropriate modification, repetition, and other forms of reinforcement of the stimuli.

The inability to inhibit already learned responses hinders the broadening of the available repertoire of responses in the same situation.

The main handicap is represented by the diminished capacity in abstracting and generalizing from experience, due to the deficit in verbal ability. The lessened permeability between cognitive functions results in monotonous thinking and lessened flexibility and inventiveness, as compared with normal children of the same mental age.

Jean Piaget's developmental psychology. The work of Jean Piaget in Switzerland is compared by some to Freud's monumental contribution. Almost singlehandedly, over a span covering half this century, Piaget evolved a comprehensive theory of intelligence and the process of acquiring knowledge. Although his work shares many ideas with the learning theory, the Russian theory of intelligence, and ego psychology, to mention just a few, it remains a unique, unparalleled study of the function and development of the human mind. Although Piaget was chiefly concerned with the workings of the normal mind, his theory and methods of investigation are of great potential use in the study of the defective or subnormal mind as well. A brief description of the basic aspects and terminology of Piaget's work must necessarily precede any explanation of the possibilities of its application to the field of mental retardation.

Piaget views the evolving intelligence as a result of a continuous interaction between the individual and his environment. The active attempt on the part of the individual to mold and adapt the external en-

vironment to his own needs is called assimilation. The process of adjusting oneself to the external environment is called accommodation. The continuous reciprocal interaction between the individual and his environment, if harmonious, leads to an equilibrium, or adaptation. This, in turn, gives rise to a new advance in the ever unfolding process of intelligent functioning, characterized by a specific behavior pattern, or schema. These schemata do not remain static but undergo further changes and differentiation as the interaction between the individual and his environment continues, leading to new equilibria and new and increasingly complex schemata. The interplay among the individual schemata leads to gradual integration and generalization of behavior and the thinking process.

(In this ever expanding dynamic process of evolving intelligence, Piaget distinguishes several stages, characterized by distinct types of behavior and thinking. The progression from one stage to the next more complex one is an orderly, predictable process, although the rate of this progress varies with the child's basic neurophysiological endowment, maturation, experience, and appropriate social interaction. The major periods in Piaget's model of intelligence development are: (1) the sensorimotor stage (birth to 1½ years), (2) preoperational stage, subdivided into the preconceptual stage (1½ to 4 years) and the intuitive stage (4 to 7 years), (3) the stage of concrete operations (7 to 11 years), and (4) the stage of abstract operations (11 years onward). The stages represent a detailed analysis of the developing thought process, from the reflex behavior of the infant to the abstract thinking of the adolescent.)

Unlike most psychologists, Piaget is not primarily interested in the content of the child's performance, which permits measuring and quantification. Rather, he is interested in the thought process underlying the child's functioning. Viewed from this vantage point, each behavioral item, even if functionally meaningless, assumes importance as representative of the child's thinking, however primitive. For instance, the seemingly bizarre repetitious hand movements of an infant are seen as attempts to substitute a magic, ritualistic procedure for a desired act, such as reaching for a favored toy that is unavailable at that time.

Piaget's concepts have already been applied to the study of the mentally retarded. They represent a more fruitful approach, especially to the severely and moderately retarded, than the traditional testing methods, which become unreliable below the I.Q. of 50. Rather than describe a retarded individual in terms of a "magic number" that implies a defined store of knowledge, it is easier and more useful to describe his functioning in terms of his arriving at a certain stage of his intellectual development, characterized by a specific behavior and reasoning process. Thus, the profoundly retarded individual may be viewed as arrested or fixated at the sensorimotor stage of de-

velopment; the moderately retarded person is capable of reaching only the intuitive and preconceptual stages; the mildly retarded person does not advance beyond the stage of concrete operations; and the borderline retarded individual stops at the simpler levels of abstract thinking.)

The mannerisms so often seen in profoundly retarded children, which baffle students of human behavior, become clearer when compared with the very similar behavior of a 7- to 8-month-old infant and may be regarded as quite purposeful in Piaget's framework of the developing mind. Since this manneristic behavior of the profoundly retarded is used so often to obscure and obfuscate the problem of childhood psychosis and infantile autism, it is to be hoped that, in time, Piaget's concepts will shed some light on the still very dark no man's land bordering childhood schizophrenia, infantile autism and mental retardation.

Diagnostic factors

History. Although caution is indicated in taking history from a parent, it often remains the only source of information. The history of pregnancy, labor, and delivery, the consanguinity of the parents, and the presence of hereditary disorders in their families deserve particular attention. The parents may also provide information about the child's developmental milestones. This area is especially subject to distortions, due to parental bias and anxiety. History is particularly helpful in assessing the emotional climate of the family and their sociocultural background, which play an important part in the evaluation of clinical findings.

Physical examination. This has to include a careful observation of the child's behavior level of activity and the quality of his interaction with his parents, and other people, as well as inanimate objects. Various parts of the body may have certain characteristics commonly found in the mentally retarded due to prenatal causes. The configuration and size of the head offer clues to a variety of conditions, such as microcephaly, hydrocephalus, and Down's syndrome. The patient's face may have some of the stigmata of mental retardation, which greatly facilitate the diagnosis. Some of the facial signs are hypertelorism, flat nasal bridge, prominent eyebrows, epicanthal folds, corneal opacities, retinal changes, low set and small or misshapen ears, protruding tongue, and disturbance in dentition. Facial expression, such as looking dull, may be misleading and should not be relied on without other supporting evidence. Color and texture of the skin and hair, high arched palate, the size of the thyroid gland, the size of the child and his trunk and extremities are further areas to be explored. Measurement of the head circumference is an essential part of the clinical investigation.

Dermatoglyphics, or the handprinting patterns, may offer another diagnostic tool, since uncommon

ridge patterns and flexion creases are often found in retarded children. Abnormal dermatoglyphics may be found in chromosomal disorders and in children who were infected prenatally with rubella.

Neurological examination. The incidence and severity of neurological signs generally rise in inverse proportion to the degree of retardation, but there are many cases of severely retarded children without neurological abnormalities. Conversely, about 25 per cent of all children with cerebral palsy have normal intelligence.

The disturbances in motor areas manifest themselves in abnormalities of muscle tone (spasticity or hypotonia), reflexes (hyperreflexia), and involuntary movements (choreoathetosis). A lesser degree of disability in this area manifests itself in clumsiness and poor coordination.

The sensory disturbances may include hearing difficulties, ranging from cortical deafness to mild hearing deficit. Visual disturbances may range from blindness to disturbances of spatial concepts, design recognition, and concept of body image.

Paine advanced the knowledge of the evolution of postural reflexes in infants, which may help the examining physician in his prognosis. Caution, however, is indicated, since some children who initially present various motor abnormalities later show no abnormal motor signs and may not be mentally retarded.

Hyperirritable infants, jittery or convulsing with asymmetrical neurological signs, need careful attention, since about half of them may be brain-damaged in later life. The infants with the poorest prognosis are those who manifest a combination of inactivity, general depression, and exaggerated response to stimuli.

In older children, hyperactivity, short attention span, distractibility, and a low frustration tolerance are further hallmarks of brain damage.

In general, the younger the child at the time of investigation, the more caution is indicated in prediction of future ability, since the recovery potential of the infantile brain is very good. Following the child's development is probably the most reliable approach.

Pneumoencephalogram is somewhat hazardous and seldom indicated in the evaluation for mental retardation. The occasional findings of internal hydrocephalus, cortical atrophy, or porencephaly in a severely retarded, brain-damaged child are not considered very contributory to the general picture.

Skull x-rays are usually done routinely but are illuminating only in a relatively few conditions, such as craniosynostosis, hydrocephalus, and several others that result in intracranial calcifications. These include toxoplasmosis, tuberculous sclerosis, cerebral angiomas, and hypoparathyroidism.

The electroencephalogram (EEG) is best interpreted with caution in cases of mental retardation. The most notable exceptions are patients with hyp-

sarrhythmia or *grand mal* seizures, where the EEG may help establish the diagnosis and suggest treatment. In most other conditions, one deals with a diffuse cerebral disorder that produces nonspecific EEG changes characterized by slow frequencies with bursts of spikes and sharp or blunt wave complexes. The confusion over the significance of the EEG in the diagnosis of mental retardation is best illustrated by the reports of the frequency of EEG abnormalities in Down's syndrome that range from 25 per cent to the majority of patients.

Laboratory procedures. These include examination of the urine and blood for a host of metabolic disorders. The recently described enzymatic abnormalities in chromosomal disorders, notably Down's syndrome, promise to become useful diagnostic tools. The determination of the karyotype in a suitable genetic laboratory is indicated whenever a chromosomal disorder is suspected.

Hearing and speech evaluations. These should be done routinely. The development of speech may be the most reliable single criterion in the investigation of mental retardation. Various hearing impairments are often present in the mentally retarded; on the other hand, they may, in some instances, simulate mental retardation. Unfortunately, the commonly used methods of hearing and speech evaluations require the patient's cooperation and are often unreliable in the severely retarded.

Psychiatric examination. The psychiatric examination of mentally retarded children does not differ essentially from such examination of children with normal intelligence. The similarity decreases, however, in direct proportion to the severity of the mental defect. In no other category, except perhaps with psychotic children, is nonverbal communication and careful observation of the patient and his activity of greater importance.

The psychiatrist's contribution should always include study of the interpersonal aspect of the retarded patient's personality development. The way he reacts to both human and inanimate objects and how he relates to the examiner and to his mother or caretakers may tell most about his social maturity. Just as with infants and young children, it may be useful to examine even the older retarded patients with and without a parent or a parent substitute in evaluating dependency status and response to separation.

The child's control over motility patterns should be ascertained, and clinical evidences of distractibility and distortions in perception and memory may be evaluated. The use of speech, reality testing, and the ability to generalize from experiences are important to note.

The nature and maturity of the child's defenses, particularly the exaggerated or self-defeating uses of repression, denial, introjection, and isolation, should be observed. Sublimation potential, frustration tolerance, and impulse control, especially over motor,

aggressive, and sexual drives, should be assessed. Also important is self-image and its role in the development of self-confidence, as well as assessment of tenacity, persistence, curiosity, and the willingness to explore the unknown.

The severely retarded child presents the greatest challenge to the examiner. Bizarre, primitive, and seemingly purposeless behavior is often difficult to interpret. Categorizing the patient's observable behavior in response to the examiner's interaction with him, or independent of it, using as a model the developmental examination of infants, may help to systematize observations and provide a reasonable estimate of the patient. It is helpful for the psychiatric examiner to combine appropriate components of neurological and psychological examination methods with his own approaches.

In general, in the psychiatric examination of the retarded child, there should be a picture of how the child has solved the stages of personality development. From the areas of failure or regression, it is possible to develop a personality profile of a type that allows for more logical planning of management and remedial approaches.

Psychological examination. The examining physician may avail himself of several screening instruments, such as those developed by Gesell, Caldwell, Illingworth, and Knobloch, that are useful for infants and toddlers. As in so many areas of mental retardation, there is a heated controversy over the predictive value of infant psychological tests. The correlation of abnormalities during infancy with later abnormal functioning is reported by some authors as very low and by others as very high. It is generally agreed that the correlation rises in direct proportion to the age of the child at the time of the developmental examination.

Copying geometric figures may be used as a quick screening test of visual-motor coordination. The same can be said of the Goodenough Draw-a-Person Test, Kohs Block Test, and geometric puzzles.

Psychological testing, performed by an experienced psychologist, must be considered a standard part of an evaluation for mental retardation. The Gesell, Bayley, and Cattell tests are most commonly applied in infants. For children, the Stanford Binet and the Wechsler Intelligence Scale for Children (WISC) are most widely used in this country. Both of these tests have been criticized for penalizing the culturally deprived child, for testing mainly potential for academic achievement rather than for adequate social functioning, and for their unreliability in children with an I.Q. of less than 50. Some people have tried to overcome the language barrier of the mentally retarded by devising picture vocabulary tests, of which the Peabody Vocabulary Test is the most widely used.

The tests often found useful in detecting brain damage are the Bender-Gestalt and the Benton Visual

Retention Tests. These tests are also applicable in mildly retarded children.

The need for new test methods. There is a need reported from many quarters for new, unconventional appraisal methods of the mentally retarded that would allow the examination of the child's strengths and handicaps in a number of areas of functioning with greater precision. Most of the existing tests give only an inaccurate, global, and somewhat amorphous picture in children with severe intellectual handicaps, in whom a precise appraisal is of paramount importance. Only the knowledge of small units of functioning may help in creating suitable specific educational programs that take advantage of the child's assets. One such approach is utilized in the Illinois Test of Psycholinguistic Abilities, which tests auditory, vocal, and motor responses, both alone and in combination. The recent application of Piaget's theory to mental retardation may represent another possible approach to this diagnostic dilemma.

Social functioning. This important area, which reflects the patient's adaptive behavior, has been relatively neglected. The most popular test that measures social functioning is the Vineland Social Maturity Scale. Based on the observations of the patient and the description of his care-taker, it assigns to him a social quotient (S.Q.). The test taps the individual's competence in meeting life contingencies and dealing with his environment. It is especially useful in the severely retarded who are untestable by other methods. The social quotient (S.Q.) should not be considered synonymous with the intelligence quotient (I.Q.).

Differential diagnostic problems. A variety of conditions may simulate mental retardation. Children who come from very deprived homes that provide inadequate stimulation may manifest motor and mental retardation that is reversible if an enriched, stimulating environment is provided in early childhood. A number of sensory handicaps, especially deafness or blindness, may be mistaken for mental retardation if, during testing, no compensation for the handicap is provided. Speech deficits and cerebral palsy will often make a child appear retarded, even in the presence of borderline or normal intelligence.

Chronic, debilitating diseases of any kind may depress the child's functioning in all areas. Convulsive disorders may give an impression of mental retardation, especially in the presence of uncontrolled seizures.

Chronic brain syndromes may result in isolated handicaps, failure to read (alexia), failure to write (agraphia), failure to communicate (aphasia), and several others, that may exist in a person of normal and even superior intelligence.

Emotional difficulties may often lead to an apparent retardation. Emotionally disturbed children do poorly in school and often perform far below their actual mental level.

An alert psychiatrist or pediatrician experienced

with normal and abnormal children is usually able to assess properly the child's mental status in most of the above-mentioned conditions.

The most controversial differential diagnostic problem concerns children with severe retardation, brain damage, early infantile autism, childhood schizophrenia, and, according to some, Heller's disease. The confusion stems from the fact that details of early history are often unavailable or unreliable, and, by the time they're evaluated, many children with these conditions manifest similar bizarre and stereotyped behavior, mutism, or echolalia and function on a retarded level. By the time these children are usually seen, it does not matter from a practical point of view whether the child's retardation is secondary to a primary early infantile autism or schizophrenia or whether the personality and behavioral distortions are secondary to brain damage or retardation on other bases. When ego functions are delayed in development or are atrophic on any other basis, the physician must first concentrate on overcoming the child's unrelatedness. The child must be reachable before one can successfully apply remedial educational measures.

Several differentiating diagnostic criteria have been suggested, such as neurological signs, EEG, withdrawal, obsessiveness, better relation to objects than to people, and retention of an intelligent physiognomy. Since these conditions may be interrelated, the diagnosis may be very difficult without an adequate follow-up. Some people use the term "atypical child," implying a common organic matrix for all these conditions. This approach has inherent dangers that always accompany the grouping of medical conditions according to one or several common symptoms. It invites diagnostic complacency and discourages efforts to find more precise diagnostic criteria.

Prevention

Primary prevention

Public education. A preventive approach to mental retardation can only succeed in an educated, enlightened community. Without wholehearted support of the people for whom it is intended, the best conceived plan is doomed to failure. Public education is of particular importance in enforcing preventive measures against mental retardation, since one has to sweep away a cobweb of superstition, inertia, and revulsion that has developed over the ages, compounding and perpetrating the ignorance in this area.

The public has to be educated that mental retardation is a symptom producing a handicap and not a curse or visitation; that, as in many other illnesses, its etiology can be studied, treatment found in some of its variants, and amelioration found in most; that mentally retarded people have feelings of love and hate, anger and compassion, and have a need for affection, comradeship, and a sense of belonging,

like all of us; and that, as citizens, they have inalienable rights, which include the best that medicine and education have to offer and the right to the pursuit of happiness, which, in the case of the mentally retarded, means a right, inasmuch as possible, to a productive existence and humane treatment.

Only when such basic issues are clarified and become common knowledge and conviction can people begin to think in preventive terms and take preventive measures seriously. As experience with mass vaccinations, venereal diseases, and prenatal care in this country clearly showed, merely to offer the means of prevention, however perfect, will be useless unless people avail themselves of existing facilities. The public attitude is of even greater importance in the prevention of mental retardation. In addition to concrete, relatively easily administered measures, such as vaccinations and screening examinations of blood and urine, the main hope lies in far more complicated measures, such as ensuring an appropriately stimulating environment for a young infant or providing an emotionally stable environment for the growing child.

Public education has to proceed on several levels—impressing school children with basic facts about mental retardation, reaching their parents through communication media and through patient personal efforts of interested professionals, going out among those of the underprivileged who are at greatest risk and trying to win their cooperation. Isolated examples of such personal crusades and their sometimes spectacular success make headlines, but, unless they become a formalized mass phenomenon, there is little hope of finding a solution to the problem of familial culturally determined retardation, which accounts for the majority of all mental retardation in the United States.

All members of the community, regardless of their socioeconomic status, have to be kept abreast of the new developments and insights, ranging from the importance of preventing measles to the modern concepts of institutional care. Significant strides have been made in the last decade or two in this field of public enlightenment, both in the awareness of various causative factors and in the need to create and support measures to prevent them. But only small inroads have been made in the most disadvantaged group.

Improvement of socioeconomic standards. Basic to any real improvement in this area is the raising of the standards of living and education among disadvantaged, forgotten citizens. There is little value in preaching about the value of proper nutrition to people who lack bare necessities or in explaining the virtues of verbal stimulation and a great variety of toys to a husbandless mother of eight, living on public assistance. One has to attack the basic social and economic conditions that give rise to all the secondary phenomena, such as malnutrition, prematurity, ob-

stetrical hazards, understimulation, and overstimulation. People who are given good vocational training that permits them to compete successfully in the labor market and be economically secure are much more inclined to think in terms of securing good health and education for themselves and their families. But half measures and superficial palliative solutions cannot be effective in interrupting the vicious self-perpetuating cycle of poverty.

Unlike the inborn errors of metabolism, in which the abnormality can be successfully treated by measures concentrating on one point in the metabolic pathway, the pathway of poverty has many defects or blocks. Only a concerted, simultaneous, vigorous effort that attacks all these points at once may drastically alter the total picture. Improvement in employment opportunities presents one such strategic point. The reform of welfare practices, to permit more than bare survival, represents another. A coordinated effort by social agencies, government authorities, and community leaders, including representatives of the poor, to strengthen family stability in slums through vigorous case work, financial aid, and rehabilitation of individual family members is of equal importance.

Only a cohesive, economically and emotionally secure family can offer the proper soil for both intellectual and emotional growth. To reach and to stabilize the family units in the slum culture requires new, bold approaches, often departing from the traditional ones in psychiatry and social work.

The securing of proper housing is another aspect of rehabilitation that is important for medical as well as social reasons. One cause of mental retardation, lead poisoning, is fostered by pica. The newly acquired knowledge about the psychodynamics of pica may be useless in the prevention of lead poisoning unless decent dwellings, free of lead paint, are provided.

Providing vigorous programs of adult education and vocational retraining and wholesome recreation for people of all ages may help to overcome the inertia and fatalistic attitudes which present the major obstacles to the implementation of preventive and corrective measures. In helping people adopt and accept modern principles of prenatal or infant care, group discussions and group lectures in small circles are far more effective than official sermons by cold, impersonal authorities who fail to bridge the gap separating the rich from the poor. Only a reawakening of a sense of dignity can provide the proper motivation for self-improvement and self-help, which are far more effective than paternalistic spoon-feeding.

School buildings, school personnel, and school programs have to be improved and enriched to reach the young. Preschool training in the early formative years needs more vigorous community assistance. Whenever possible, this should be done in close cooperation with the child's family, impressing them with its importance and patiently teaching them the

principles of healthy diet and verbal and nonverbal stimulation.

Whenever a mother is working or is unavailable, a community-supported infant and child care center, staffed by well trained educators and aided by volunteer members of the community, may provide an appropriate program. Many less affluent countries have social laws that protect the working mother by the provision of generous, paid prenatal and postnatal leaves and adequate day care centers for their infants and children located near their homes or places of work. Practices in this country are still quite antiquated and need urgent revisions.

Preventive medical measures. Improvement of prenatal care is a recognized cornerstone in all efforts to prevent mental retardation. To begin with, restricting the number of pregnancies in adolescence and after the age of 40 will reduce the risk of chromosomal aberrations and obstetrical complications. Prevention of prematurity; detection of Rh and other blood incompatibilities; adequate nutrition during pregnancy, including vitamin and mineral supplements; control of maternal diabetes, pretoxicemic states, syphilis, and other infections by appropriate medication and diet—all these no doubt help reduce the number of reproductive casualties that Pasamanick et al. showed to be responsible for a host of disorders associated with mental retardation.

Preventive obstetrical measures include good technical preparation of the delivering physician, not always available in overcrowded city and rural hospitals; reduction of the amounts of anesthetic and analgesic drugs given to women in labor, since they often have a depressing effect on the baby; a less lackadaisical obstetrical attitude toward neonatal transient apnea, which can produce lasting brain changes, despite its short duration; better monitoring of the vital fetal signs during labor; caution in the use of new drugs during pregnancy, unless their lack of harmful effects on the baby is proved beyond a reasonable doubt; and standardization of delivery records by the universal adoption of the Apgar scoring system, which may become the first *reliable* information in the natural history of mental retardation.

Pediatric preventive measures cover acute and long range problems. The measures covering acute problems include improvements in infant resuscitation techniques; early recognition of hemolytic diseases of the newborn and their vigorous and early treatment by skillful exchange transfusions and the still experimental intrauterine transfusions; early recognition of transient convulsive disorders caused by such factors as hypoglycemia, hypocalcemia, and pyridoxine deficiency and their prompt treatment. A close cooperation between the obstetrician and the pediatrician and their respective departments is indispensable in securing improvements in neonatal care.

The long range pediatric measures involve prevention of acute illnesses potentially dangerous to the central nervous system. In addition to already available vaccinations against many viral and bacterial diseases, new ones may be expected shortly, especially against German measles. Further, the supervision and, if necessary, improvement in the infant's nutritional status, especially his intake of protein, vitamins, and other essential food ingredients, is very important. Recognition and early treatment of various diseases potentially affecting the central nervous system, such as meningitis, hypernatremia, lead poisoning, and convulsive disorders, will help to reduce the number of sequelae resulting in mental retardation.

Obstetricians and pediatricians are doing a creditable job of primary prevention in their private practices, but this care is not universally available for the indigent, and most vulnerable, population. This opinion is best supported by reliable statistics indicating that in the rate of infant mortality the U.S. is in 10th place, having a worse record than far less affluent and technologically advanced nations. Another statistic indicates that in many big city slums, as many as four fifths of all pregnant women never have any prenatal care. Human social factors explain the failure to use existing free prenatal and well baby clinics. Several measures could help remedy this paradoxical situation. Providing a continuity of doctor-patient relationship in the clinics by having the same physician see a patient over a span of at least 1 year, instead of providing the prevailing impersonal assembly line atmosphere, would certainly be a major incentive to the continuity and regularity of medical care. The impersonal use of "Mother," "Miss," etc., without the addition of the family name, hardly inspires confidence or induces a resolve to follow the physician's directions or to return for the next scheduled appointment.

The role of other specialized personnel is vital to the success of any preventive mass program. The public health nurse, the social worker, the nutritionist—all can maintain a warm contact with their patients and their families, facilitating communication and ensuring a follow-up. Latest innovations in this field include a traveling well baby clinic on wheels, operating literally on the principle of reaching out into the community, and child care counselors recruited from among middle-aged, intelligent women, trained intensively in infant development and well baby care, who help spot potential distortions in the baby, in the mother, or in the mother-baby interaction and who work intensively with the mothers to help them in child rearing.

These measures may help, no doubt, but the real key to the dilemma of improving physical and mental health in indigent populations may well be in the new concept of comprehensive health programs, based at headquarters in a multipurpose community health

center or hospital and branching into the community through the use of satellite preventive clinics. Each such program encompasses a delineated part of the city, the inhabitants of which and their health status will become known to the program staff. A thorough knowledge of the community permits the early spotting of hard core multihandicapped families and other potential risks and permits zeroing in on a troubled family in a very intensive way. This kind of network will help reduce greatly the number of stragglers, the ones who skip appointments or who are too inhibited or depressed to seek help on their own. Such programs, if successful in winning over the community and its leaders, are the main hope at present for the effective prevention of much of the mental retardation in this country.

Genetic counseling. Genetic counseling, which usually involves the question of the desirability of future offspring by the parents, siblings, and sometimes more distant relatives, can be done by private practitioners and staff physicians in clinics and hospitals. Knowledge in this area is still limited, and precise data are available in only a few conditions. Thus, the amount of presently available information can be acquired and usefully applied by any practicing physician. This use has to be preceded, however, by an exact diagnosis, which may require biochemical and cytogenetic studies.

In many cases of mental retardation, the problem of genetic transmission is either unknown, unresolved, or very complex. Counseling of such cases is better left to mental retardation evaluation centers staffed by specialists in this area and equipped with a cytogenetic and biochemical laboratory, permitting the performance of specialized tests.

In the counseling of parents of patients with Down's syndrome, it is of greatest practical importance to differentiate between the cases resulting from translocation and those caused by trisomy. In the former, the risk of having a second child with Down's syndrome is 1 in 3; in the latter, it averages 1 to 2 per cent.

With some exceptions, conditions known to be caused by a dominant recessive gene are quite predictable, in that the children of affected persons have a 1 in 2 chance of inheriting the same disorder, but the asymptomatic relatives do not carry the deleterious gene.

In cases of autosomal recessive genes, the accurate prognosis is more complicated, but certain fundamental facts are known and may be used in practice. The parents of one child with such a condition run a 1 in 4 risk of having a second affected child. This is true in PKU and galactosemia. The siblings of PKU patients are heterozygous carriers in two thirds of all the cases that can be confirmed or ruled out by a phenylalanine tolerance test, but their chance of having a PKU child is only 1 in 250, provided they marry outside their own family. Equally predictable

are the sex-linked diseases, in that half the sons of a carrier mother are affected, and half the daughters are carriers.

In stating the likelihood of a second defective child, the counselor is doing nothing more than making a statement of mathematical statistical probabilities. There may be a statistical risk of 1 in 4 of two heterozygous carriers having a phenylketonuric child, for example, but the couple may be lucky or unlucky and may have either four normal or four affected children in a row. The physician's role is to present the known facts and also the uncertainties to the parents frankly and openly, to tell them what the chances are insofar as these are known, but to recognize that what to do in the presence of any particular set of odds is a parental rather than a medical decision.

Counseling the family about the procreation of the mentally retarded themselves presents several legal, ethical, and scientific problems. The severely retarded are seldom fertile, and the proof of genetic inferiority of the majority of the mildly retarded is still lacking. Regional approaches to this problem are reflected in differing state laws affecting sterilization and abortion. An increased interest in this question can be anticipated with the present trend to keep the mentally retarded within the community. An appointed panel of medical specialists and lawyers acquainted with the intricacies of this problem would seem most suitable to examine each case on its own merit and to pay attention to possible hardships to the family, the community, and the patient himself. Judicial sterilizations and abortions may be very helpful in individual cases, but their influence on the prevalence of mental retardation in the population is negligible.

Secondary prevention

Early identification and treatment of hereditary disorders. Despite considerable progress in this area, there are still only a few conditions in which early detection and treatment may prevent mental retardation. Mass screening for inborn errors of metabolism is recommended at present only for PKU, galactosemia and possibly maple syrup disease, but several other conditions may be added shortly to this list.

The simple urinary tests for PKU (ferric chloride) do not become reliable until the baby is 4 to 6 weeks old. The Guthrie bacteriological method of blood examination may help detect the condition in the 1st week of life, which is of importance, especially in indigent patients, who may not be readily available for testing after their discharge from the obstetrical unit. Dietary treatment with a low phenylalanine diet is effective in preventing at least the severe degrees of retardation and the behavioral manifestations if it is started in the first 6 months of life. This treatment carries certain hazards, and its administration re-

quires the teamwork of several specialists—physician, nutritionist, social worker, nurse—to assist the parents and to evaluate the child at frequent intervals. Such supervision is probably best carried out in specialized centers.

Galactosemia can be readily screened by using Clinitest and examining the urine for reducing substances. Treatment requires the omission of milk from the diet; several milk substitutes are readily available. Early detection and institution of treatment is effective in preventing mental retardation and other manifestations of this disease. Milk may be reintroduced into the diet in moderate quantities at the age of 4 or 5 years, since by that time the child apparently develops alternative metabolic pathways for handling galactose, but these are not sufficient to handle a quart of milk a day.

The third condition in which early diagnosis is crucial is hypothyroidism. Although diagnosis is not always easy in early infancy, careful examination, coupled with a high index of suspicion, helps the physician detect the disorder in most cases. His suspicion aroused, the physician has several tests available with which to confirm the diagnosis, such as radioactive iodine uptake, protein bound iodine (PBI), and butanol extractable iodine (BEI) in the blood. On confirmation of the diagnosis, it is essential to institute immediately vigorous treatment with thyroid extract, preferably during the first 6 months of life. Treatment started after that time seldom prevents mental retardation, although it may still mitigate the results of thyroid deficiency.

There is now dietary treatment available for a number of amino acidurias, such as maple syrup disease but, despite recent developments of several diagnostic methods, mass screening for most of these conditions does not seem justified at present.

Medical and surgical treatment of other conditions. Prompt diagnosis and treatment of bacterial meningitis with antibiotics and occasionally with steroids may prevent neurological sequelae, including mental retardation. The sequelae of viral meningocephalitis are best prevented by immunizations, since at present only supportive therapy is available, although there is some promising research in the area of antiviral therapy.

Lead poisoning, caused by the chronic ingestion of lead, should be suspected, especially in indigenous populations, in cases of unexplained vomiting, abdominal pain, irritability, failure to thrive, and encephalitic signs. At Children's Hospital of the District of Columbia, interest in the pica phenomenon led to a high index of suspicion in the staff, resulting in a rate of detection of plumbism in the clinic population exceeding by far the frequency in other pediatric centers. Prompt deleading with Versene is usually effective, but relapses are frequent, due to the personality difficulties of the mothers and continued availability of lead paint in dilapidated slum dwell-

ings. Each relapse increases the risk of permanent central nervous system damage. Effective prevention must include provision of decent, lead-free housing and intensive parental counseling.

Surgical treatment that is effective in preventing mental retardation is limited to only a few conditions. Evacuation of a *subdural hematoma* following a trauma or meningitis is a simple procedure that has to be supplemented in some cases by the excision of the membrane from the subdural space. If untreated, the condition may result in irreversible brain damage and mental retardation.

The surgical treatment of hydrocephalus is far less satisfactory. Several procedures for shunting the excess cerebrospinal fluid to various areas of the body are employed with varying success in different centers, but the over-all results are still rather disappointing.

Craniosynostosis, premature closure of the suture lines, may be corrected by a craniectomy. If performed early in infancy, the operation will allow the rapid brain development of this period and prevent damage caused by its restriction. It is important not to confuse this condition with congenital microcephaly, in which surgical measures are useless.

Excision of the epileptogenic focus in temporal lobe epilepsy may be effective in cases that fail to respond to anticonvulsant medication.

The results of various experimental procedures designed to increase the blood flow to the brain and thus improve mentation have not been very promising to date.

Early recognition and handling of children with isolated handicaps. There is a growing recognition of the existence of a large number of infants and children with isolated motor, sensory, perceptual, behavioral, and intellectual difficulties. By some estimates, the number comes to about 5 per cent of the general school population. Etiology varies from hereditary factors to mild brain damage due to obstetrical insults. The early history in many of these children suggests some prenatal, perinatal, or postnatal difficulties, and the resulting variety of symptoms gives support to the concept of a continuum of reproductive casualty. In as many as half of these patients, the early history is noncontributory, and one could think, in mild cases, in terms of delay of maturation of the CNS.

The perceptual difficulties may manifest themselves in disturbances of body image, spatial relationships, and design recognition. These are often accompanied by EEG changes and give rise to many learning problems. Perceptual training aimed at overcoming these difficulties is still in the experimental stage, but it is to be hoped that practical methods in this area will emerge shortly, with specific recommendations as to appropriate play materials and play methods.

In frank sensory deficits, such as deafness or blindness, the child can be helped by intensive use

of the remaining normal sensory pathways, which enables the developmental and socialization process to progress along normal lines by maintaining communication between the child and his environment. Failure to recognize these handicaps early and to employ compensatory avenues of sensory input often results in preventable mental retardation and withdrawal.

Deficiency in the motor area may manifest itself as general clumsiness and poor coordination, which interfere with the mastery of motor skills, such as writing. Making allowances for this will prevent penalizing the child and holding him back in school. Early recognition of this handicap in a younger child helps the parents delay introduction of such activities as bicycle riding or ice-skating to spare the child the sense of failure.

Isolated scholastic difficulties may involve number concepts, reading, handwriting, or abstract thinking. Help in these areas, by way of small groups or individual tutoring, may make it possible for the child to keep up with his age-mates. There are a number of teaching methods available to deal with these learning problems, and it is incumbent on school officials to provide such specialized services.

Distortions in reactivity patterns, such as hypersensitivity and hyposensitivity to various sensory stimuli, may be overcome if recognized early and treated appropriately. An infant or young child with a low arousal threshold does better with a lowered intensity of environmental stimulation. The reverse holds true for children with a high arousal threshold.

Distractibility and hyperactivity due to mild brain damage or to unspecified constitutional factors present stumbling blocks to learning and are starting points of child-parent and child-teacher conflict, resulting in a behavior problem. Effective medical measures include the use of amphetamines, phenothiazines, and some antihistamines. The educational measures usually employed aim at increasing the child's attention span by limiting his visual field to only a few items essential to the task at hand. Small classes for such children allow the teacher more flexibility and a more liberal behavior policy than is possible in a regular large classroom. The parents' attitude toward the child improves as they are better able to understand the causes of his erratic behavior.

The problem of aphasia in children is the most difficult and controversial of all manifestations of minimal brain syndromes. The difficulty is primarily on the receptive level and may occur at any point of the central auditory pathways, resulting in a variety of disorders in the reception of auditory stimuli. Expressive aphasias, which prevent the child from expressing his thoughts while allowing him to perceive and interpret sounds correctly, are relatively rare in children. Aphasias may often be masked by mental retardation or autistic withdrawal and, if not recognized and treated early, may well result in these conditions. The training of aphasic children, aiming

chiefly at maintaining communication, requires highly specialized personnel and is done best under the aegis of a hearing and speech department in an academic center.

All these handicaps, regardless of etiology, are very taxing to the child, his parents, and his teachers. The resulting conflicts may contribute to the development of serious psychiatric difficulties, such as uncontrollable aggressive behavior, difficulties in group adjustment, withdrawal, and passivity. Despite a normal intellectual potential, the children may function on a retarded level if continued in an unsuitable school program. The emotional difficulties and the retardation are best prevented by an early diagnosis followed by long term parental counseling and guidance by the physician or appropriate paramedical or educational specialists. Psychotherapy is required for only those few patients who have already developed serious school difficulties. Environmental adjustments, such as the establishment of a routine, flexible but firm limit setting, appropriate regulation of the sensory input, and opportunity to burn excess energy, often result in a rapid, striking improvement, particularly in infants and young children.

Early identification and treatment of the culturally deprived child. Infants from disadvantaged, deprived backgrounds are indistinguishable from their more fortunate age-mates in the 1st year of life. They often score even higher than middle class children on infant development tests, which are all heavily weighted with sensorimotor items. However, in the 2nd year they begin to fall behind, and by the age of 2 or 3 years they show delay in speech development, less originality and spontaneity in play, and a constriction, rigidity, and general impoverishment of the thinking process. It is estimated that, by the time deprived children begin their school career, the gap separating them from more privileged children widens to about 1 to 2 years.

The early recognition of environmental deprivation by the physician requires his knowledge of both normal and deviant child development. Periodic developmental examinations or screening by physicians or other trained professionals is the best guarantee of early detection.

The treatment of culturally determined retardation aims at filling the gap by providing more sensory, verbal, and emotional stimulation and by the introduction of new, pleasurable experiences and useful skills to widen the child's intellectual horizon. Appropriate counseling and guidance may make it possible to conduct such enrichment programs at home, but often a well staffed child care day center provides the most appropriate setting for the mental rehabilitation of these children. There is reason to believe that an intensive, systematic application of such enrichment programs throughout the country may reduce the number of mentally retarded by at least 50 per cent.

The environmental hazards for children from deprived backgrounds are not limited to the preschool age. They enter school under serious handicaps, and only a rich program conducted by experienced teachers in small classes may bring them up to the expected grade level. Unfortunately, these children often attend schools housed in dilapidated buildings, in crowded classes conducted by inexperienced teachers overwhelmed by the magnitude of their task. As a result, the prevailing standards are below the national average, and the initial gap widens, leading to a relative retardation.

The detection and treatment of emotional difficulties in young children may prevent serious learning difficulties in the future. This requires more attention being paid to the child's personality development in the course of well baby and child health care. The emphasis on detection has to be coupled with a greater availability of facilities and staff for parent counseling and psychotherapy.

Tertiary prevention

Treatment of behavioral and personality difficulties. The emotional problems of the mentally retarded differ in many ways from similar ones of children with normal intelligence. Consequently, they often require methods of treatment not commonly employed with the latter group. This applies particularly to the moderately or severely retarded; the mildly retarded may profit greatly from conventional play and activity group therapy.

The chief obstacle to effective psychotherapy is the difficulty in establishing communication with the child. Meaningful verbal interchange is difficult or impossible, due to faulty language development and impairment of concept formation. The latter often interferes with the use of toys and play situations as symbolic representations of the child's concerns. The therapist has to operate on a very concrete level in order to reach the child and above all has to be flexible and pragmatic. Methods used with disturbed infants and young children may be usefully applied, aiming toward making the child comfortable and relatively free of anxiety. Physical contact may be indicated in some children, but others react to it with panic and disorganization. Repeated clarification of situations and the therapist's reactions and intentions is very reassuring. Engaging the child in shared activities is probably the most effective way to establish a meaningful relationship. Unlike that in conventional psychotherapy, firm limits have to be established and adhered to consistently, particularly in children with difficulty in impulse control. Verbal and nonverbal reassurance and praise should be used generously, and situations should be set up that permit the patient to succeed. In addition, concrete evidence of affection in the form of small gifts, toys, and candy is very helpful, as are such pleasurable activities as trips to the drug-

store, park, playground, etc. Many would call it relationship therapy or good mothering, but it certainly is psychotherapy in the broad sense of the word.

Counter-transference problems may be serious and often resemble those encountered in the course of treatment of psychotic children. The patience and ingenuity of the therapist are taxed much more in cases of mental retardation associated with psychosis. As in the treatment of adult schizophrenics, the therapist, in order to be effective, may require certain personality attributes that are yet to be determined but that probably include spontaneity, flexibility, and tolerance.

Individual and group psychotherapy may be effective only if it is an integral part of a structured program involving the total milieu of the child, including his home and day or residential school. Establishing an appropriate school program, matching the child with suitable teachers and child care workers, establishing order and consistency at home, and building an appropriate recreational program are all essential components of such a total program, which has to be coordinated and unified. One may see the psychiatrist's role primarily as that of coordinator and guide of such programs.

Drugs play an important role in the psychiatric treatment of the mentally retarded. Many reports of institutionalized children describe excessive drug dosage, often 10 to 20 times higher than is usually recommended. Since most of the ataractic drugs are not without hazards, caution is indicated, and excessive dosage should be discouraged. This is especially true of children living at home or in institutions without constant medical supervision. Phenothiazines are the most widely used and probably the most effective drugs. Hyperactive, restless children often profit from amphetamines. Antihistamines have also been applied by some with good results. Barbiturates are usually contraindicated, since they often produce the unexplained paradoxical effect of increasing the restlessness and tension.

Parent counseling. Parent counseling is of paramount importance. The approach to parents has to be flexible and pragmatic. Some parents need help only in coming to grips with their feelings about the child and require a conventional dynamic casework approach. Judiciously used support, reassurance, guidance, and practical advice as to the management of the child are often indicated. Homemaking services, temporary placement of the child in institutions, and similar arrangements increase the parents' effectiveness by giving them periodic relief. Group therapy, which permits the sharing of burdens and getting reassurance from similarly afflicted parents, is especially effective with parents of retarded children, and this explains the rapid proliferation, success, and popularity of parents' groups in the last 2 decades.

The problem of institutionalization is probably

the most difficult aspect of counseling and guiding parents of retarded children. The huge, impersonal, understaffed state institutions for the retarded are the outgrowth of the nihilistic and pessimistic thinking about mental retardation in the past. The physicians who then recommended immediate hospitalization following the diagnosis were in accord with the contemporary medical thinking and community attitudes. Today the public's philosophy in this area is undergoing a radical change; it was given impetus by the research on maternal deprivation and the new community orientation on mental retardation.

Early institutionalization (before age 6) is seldom indicated and takes a heavy toll in the social and the intellectual development of the child. Many parents might keep the retarded child at home, at least for the first few formative years, if they have the appropriate guidance, support, and interest of the physician. There are instances, of course, where the family equilibrium is so shaky and the emotional balance of the family members so precarious that early removal of the child from the home is necessary in the interest of the family. This, however, is the exception rather than the general rule.

Effective parent counseling by the physician requires his thorough knowledge of the appropriate community agencies and resources in his area, such as educational facilities, institutions, vocational rehabilitation, public school classes for the retarded, and sheltered workshops.

Modern concepts of institutional care. The early pioneers of residential care for the mentally retarded stressed education and training. The failure of early exaggerated hopes to materialize caused a shift of emphasis. Institutions took on a custodial character, protecting the retarded individual and isolating him from the community. Today the thinking in this field has come full circle. Training, education, treatment, and rehabilitation are once again the primary goals. This radical change in orientation closely parallels a similar revolution in the concept of mental hospitals. Both areas now share similar goals of intensive treatment and reintegration of the patient into the community. The main obstacle to this goal is the large size of most state institutions and their inclusion of patients of all ages with all degrees of mental and physical handicaps, which precludes individual attention except for the most promising patients, that is, the least retarded.

The realization that mentally retarded people have need of affection, approval, and dignified treatment prompted the current gradual change of institutional settings. Instead of huge, sterile barracks with endless rows of beds and little else, a homelike setting is advocated, planned around smaller units that include living rooms, playrooms, separate kitchens and dining rooms, and attractive bedrooms. The homelike atmosphere is underscored by the careful choice of personnel for such units or cottages. Their emotional

stability and motivation guarantee their effectiveness as substitute parents. Dealing with a relatively small stable group of children and adults helps the retarded child, especially in his social maturation, in the areas of impulse control and the development of meaningful human relationships. The small group concept is extended to classrooms, workshops, and recreational facilities. Children are grouped according to age, degree of retardation, and type of handicap. Only such grouping permits the tailoring of the program to fit the needs of the individual child.

Contact with the child's family should be maintained primarily through the location of residential care centers within the community, by liberal visiting hours, and by the encouragement of regular, frequent home visits whenever feasible.

In addition, a number of other facilities may serve the needs of mildly retarded individuals who cannot be cared for at home and yet do not require a full time residential center. These facilities are best located in the vicinity of a larger institution or health care center, where needed services may be obtained without delay. The half-way house or hostel originated in Western Europe and proved very useful in the handling and rehabilitation of chronic schizophrenic patients. It also seems ideally suited for adolescent and adult mildly retarded individuals who require a minimum of supervision and can work in the community. Patients of the same age group who require more guidance may do well in sheltered workshops, where they are engaged in productive work geared to their skills, under close supervision. Recreational day centers for children of all ages give parents a welcome relief and an opportunity to lead a normal life and may enable them to keep even a disturbed child at home. The parent can be assisted in home care by a number of specialized services, such as visiting nurses, social workers, and visiting housekeepers, and by an opportunity for temporary short term placement of the retarded child in an institution or summer camp in times of crisis and increased family tension.

At present, there are about 200,000 mentally retarded individuals in residential care, which amounts to about 4 per cent of the estimated total retarded population. Recent experience clearly shows that the introduction of modern diagnostic, treatment, and training facilities into the community reduces the need for long range institutional placement, which in time will probably be limited to bedridden, profoundly retarded patients and those with severe emotional disturbance.

Vocational rehabilitation. The area of vocational training and rehabilitation has been neglected in the over-all educational program for the mentally retarded. The stress has been on academic skills, leading to frequent disappointments because of negligible gains, despite intensive and patient efforts. Since recent experience indicates the capacity of almost all

mentally retarded to be productive, the emphasis is gradually shifting to vocational and provocational training, especially within the adolescent group.

To be effective, such programs have to include a variety of training possibilities tailored to the individual's skills and previous experiences. A detailed assessment of the patient's strengths and defects in functioning must precede any sensible program planning. As in all other phases of education and training, the success of such programs depends largely on a small instructor-trainee ratio, on the amount of individual attention available, and on the support of the community. Vocational services should include counseling of the trainees and their families and an employment placement service.

Physical rehabilitation. The mentally retarded, especially those in the moderate or severe group, are often afflicted with a variety of physical handicaps that further reduce their potential for normal functioning. Sensory deficits, especially of vision and hearing, require correction whenever possible and special training if the damage is irreversible. Blind, deaf, or aphasic children do better as a rule in specialized centers, with special training and educational facilities. Children with motor difficulties often require orthopedic services as well as physical therapy. For such children, the unavailability of crippled children's programs to the retarded is particularly to be deplored.

Awareness of the unfavorable body image of the mentally retarded has recently prompted some consideration of the role of plastic surgery in correcting some of the stigmata of the mentally retarded for cosmetic reasons.

Special education. The education of the mentally retarded shares, with the education of normal children, the goal of preparing the student for future satisfactory life adjustment and helping him develop his full potential. There is often disagreement among educators, however, as to what presents a reasonable objective for a given child and the best way to achieve it. This has resulted in many rival theories and curricula, which can confuse rather than guide the educator.

It may help bring the controversy into historical perspective to remember that the principles of special education laid down by the early pioneers over a century ago are still among the best guidelines available. Recent knowledge of the importance of neurophysiological, cultural, and affective factors in the learning process confirms rather than detracts from their validity.

Itard's five objectives in the management of the wild boy of Aveyron were: "(1) To render social life more congenial to the boy by making it more like the wild life he had recently kept. (2) To excite his nervous sensibility with varied and energetic stimuli and supply his mind with the raw impressions of ideas. (3) To extend the range of his ideas by

creating new wants and expanding his relations with the world around him. (4) To lead him to the use of speech by making it necessary that he should imitate. (5) To apply himself to the satisfaction of his growing physical wants, and from this to lead on to the application of his intelligence to the objects of instruction" (Kanner).

Guggenbühl stressed "(1) the development of sensory perceptions beginning with primary excitations and progressing to more refined complex stimuli, (2) attempts to awake the soul through habituation to regular routine, memory exercises, and speech training" (Kanner).

And Séguin, in his classical textbook, published in 1846, said: "To be physiological, education must at first follow the great natural law of action and repose, which is life itself. To adopt this law to the whole training, each function in its turn is called to activity and to rest; the activity of one favoring the repose of the others; the improvement of one reacting upon the improvement of others; contrast being not only an instrument of relaxation but of comprehension also. The general training embraces the muscular, initiative, nervous, and reflective functions, susceptible of being called into play at any moment" (Kanner).

The preceding passages sound surprisingly modern and seem in perfect accord with our views concerning sensory stimulation; the value of a familiar, stable environment; the intersensory organization as a precursor of intelligence; the role of motivation; the value of routine and of stimulus variation; the importance and promotion of speech; and the Pavlovian bipolar view of the higher nervous activity, oscillating between the states of excitation and inhibition, to mention just a few.

The role of emotional ties between the student and the instructor is not explicitly stated by these pioneers, but is implicitly conveyed by their conduct. Itard devoted 5 years exclusively to the training of the wild boy of Aveyron, and Séguin spent 18 months on the treatment of an idiotic child.

The present system of special education employs the division between the educable—those capable of grasping the rudiments of academic skills—and the trainable—those capable of acquiring only basic social habits. The general characteristics of the retarded group, particularly where there is also brain damage, include rigidity and concreteness of thinking, distractibility, and poor motivation. (The methods applied to overcome these handicaps vary, but they all share several general principles strikingly similar to those mentioned above: limiting the number of available stimuli; gradual introduction of new, more complex experiences; emphasis on success to bolster motivation; and utilization of several mutually reinforcing approaches—visual, auditory, tactile, kinesthetic, and verbal—in the teaching of a single concept.)

A few of the new trends in special education may be mentioned here: (1) the lessened emphasis on academic performance and greater stress on prevocational and vocational training and on practical life experiences; (2) the attempt to recognize small rather than global units of the child's functioning, permitting the precise identification of his assets and building an individual program around these assets; (3) the introduction of operant conditioning techniques in the training of the severely retarded, based on the principles of reinforcement of desired behavior by reward, reported as less effective in retarded children than in animals but useful in the habit training of this group; (4) the recognition of the value of psychiatric guidance and consultation by teachers and instructors.

The current emphasis on preschool education may be considered as the most important innovation in the field of special education. It is now generally recognized that early intervention may accelerate mental and social development and break up or correct faulty learning habits. Some people advocate such intervention in infancy, regarding this age group as most malleable and responsive to environmental changes.

Legal Aspects

The more humane approach to the mentally ill and the mentally retarded in the 19th century had a strong impact on the law throughout the civilized world. Concern for the weak, minors, and the naturally disabled is increasingly reflected in changing laws and statutes.

Many inherent difficulties greatly complicate the legal issues of mental retardation. The most formidable obstacle to the uniformity of opinion and procedures has to do with the lack of clarity in the areas of definition and classification. It is still controversial as to what criterion should be used by the legal authorities to classify a person as mentally retarded and to determine the degree of his handicap and legal responsibility. The common use of the intelligence quotient is being challenged by many lawmakers who prefer to consider the current degree of social adjustment and competency. Regardless of the choice of criteria, the issue is further complicated by the realization that mental retardation is not a static condition but rather one that is subject to change in response to environmental as well as maturational factors. The most expedient and just approach to the definition of mental retardation for legal purposes has to include the individual's level of present functioning and his intellectual potential as measured by various standardized tests, which may project the individual's functioning in the future.

Civil law. One of the most important legal issues in mental retardation has to do with residential care. Whenever possible, one prefers a voluntary admission to an involuntary commitment. This is often

complicated, however, by the degree of retardation or emotional upheaval that precludes a conscious choice on the part of the retarded individual. In the case of a minor, the parents usually assume the responsibility for the decision, and in cases of parental neglect or absence, the child falls under the general jurisdiction of the juvenile court and other official protective services. In the case of an adult patient, a legal procedure to determine his incompetency is often necessary before an involuntary commitment takes place.

Until recently, a patient admitted to a state institution for the mentally retarded often remained there for the rest of his life. Under the impact of new knowledge, however, an increasing number of residential patients are released into the community. Since permanent institutionalization is no longer considered beneficial or necessary for most mentally retarded, it is important to retest the mentally retarded patients in institutions at regular intervals to guarantee their basic right to live in a normal community if their general level of functioning improves sufficiently to permit it. This is obviously one of the many areas in which lawmakers will look for assistance from the medical and behavioral sciences.

Recently, it became obvious that most people in state institutions are there for two reasons: (1) the lack of proper educational, vocational, recreational, and counseling facilities in most communities, and (2) emotional difficulties. To guarantee the rights of the mentally retarded, the law would have to oblige the communities to create and improve appropriate facilities, including opportunities for psychiatric treatment.

The problems of guardianship and legal competency are often complicated, and a highly individualized approach by the legal authorities is most desirable. It is of great importance to determine the degree to which mental retardation interfered with the exercise of good judgment by the given individual. This will then be decisive in delineating the areas of social incompetency requiring decisions by third parties. It is preferable for the court to specify the areas to be included in the guardianship. A flexible plan may prevent the mentally retarded individual from administration of his property without restraining him from decisions concerning his person. Specific decisions may be required in matters such as signing of legal documents, voting, driving, marriage, adoption, and eugenic sterilization. The court will have to rely in all these matters on professional opinion, and the role of the psychiatrist as an expert in the area of human behavior is of crucial importance in helping the legal authorities arrive at a just solution. The usefulness of psychiatrists and of other members of a professional team—psychologists, social workers, vocational specialists—will largely depend on their acquaintance with mental retardation in all its complexity.

To safeguard the rights of the mentally retarded, a protective government agency is needed to supervise individual cases, especially when the immediate family fails to assume the responsibility. Such an agency might help a retarded person challenge court decisions through ordinary legal channels and should be available for consultation to the patient, the family, or other legally approved guardians.

Criminal law. This area is even more controversial than that of civil law because, in addition to the rights of the individual, public safety and the rights of the community are of great concern. Since the middle of the 19th century, there has been a growing awareness in the Anglo-Saxon law of emotional and intellectual handicaps, reducing the criminal responsibility of some members of society. Another growing trend is to view the sentence as a therapeutic and rehabilitative rather than a punitive process.

The paramount issue is that of competency to stand trial. Here again, the court will have to rely on professional, expert opinion, and the role of the psychiatrist in this context is quite obvious. His testimony will help the court to determine the defendant's capacity to exercise sound judgment, to highlight the circumstances leading to and surrounding the crime, and to decide on appropriate measures designed to be therapeutic. The psychiatrist will also be called on to help determine what degree and extent of isolation of a mentally retarded criminal is necessary for the protection of the community.

The previously mentioned protective government agency should attempt to ensure the legality of the judicial proceedings, the validity of the defendant's confessions, and the availability of proper legal counsel. This agency should also supervise the existing therapeutic rehabilitative facilities in state institutions, prisons, and the open community. A wide range of facilities within a state, including foster homes, half-way houses, and vocational training, will help the court reach a just decision.

The actual implementation of these measures varies greatly in the United States, with some striking differences between states and communities. Further improvement requires a general public enlightenment to help overcome some deeply rooted fears and prejudices. In addition, it requires a greater involvement and cooperation in the problem of mental retardation on the part of the legal, medical, and paramedical professions. The most perfect law will be useless without a trained interdisciplinary team familiar with all the facets and ramifications of mental retardation. The growing awareness of the need for change and reform of legal statutes in accord with contemporary knowledge of the nature of mental retardation found expression in several studies addressing themselves to this complex but necessary task, of which the most publicized was the Re-

port of the Task Force on Law of the President's Panel on Mental Retardation.

Role of the Psychiatrist

In the past, when organic approaches dominated the field of psychiatry, mental retardation was considered an integral part of mental illness; *dementia* and *amentia* were viewed as not very far apart. The predominantly dynamic orientation of the early part of our century was one of several factors responsible for the present dichotomy between the two disciplines. The change in psychiatric thinking, which now stresses the interplay among biological, psychological, and cultural factors in the shaping of human personality, permits the reintegration of mental retardation into psychiatry, the latter seen broadly as a science concerned with human behavior. The normal and deviant behavior of the majority of the mentally retarded shares many features with that of people with normal intellectual endowment. The problems are often similar, except for the timetable of their occurrence. The methods applied for the prevention of emotional difficulties in normal children seem to be equally effective in the mildly retarded group, which comprises about 85 per cent of the retarded. The behavior disorders of the severely retarded often resemble those presented by psychotic children and may call for similar therapeutic measures.

Increased understanding of personality development and its many biological and environmental determinants can be usefully applied to the study of personality development in the mentally retarded. Psychiatrists, especially child psychiatrists, seem uniquely equipped to contribute to the clarification of our basic thinking in this still controversial field. Conversely, the detailed study of the mentally retarded may increase our general knowledge of the reciprocal interaction of cognitive and affective factors in the process of learning and of the biochemical and neurophysiological corollaries to the adaptation of the human organism to stress.

The many hazards in the process of personality development faced by the mentally retarded point to the pivotal role of the psychiatrist in the prevention of retardation, as a consultant to other physicians, educators, and rehabilitation programs and as a direct participant, when indicated, in the treatment, care, and rehabilitation of the retarded. His training helps him recognize the innate developmental forces and environmental influences. By timely intervention, he may direct the handling of distorted personality patterns so as to identify and help interrupt patterns of pathological interaction between the retarded patient and his family or his care-takers. His training in identifying sources of anxiety and the nature of defensive maneuvers helps him in bringing about a reduction of tension, thus promoting emotional maturation and motivation for learning.

The study of the theoretical and practical aspects of mental retardation will greatly benefit the psychiatric trainee by offering him a unique exercise in nonverbal communication; an opportunity to study the evolution of defenses in their primitive forms, rarely seen in normal children and adults; and a dramatic demonstration of the interplay of dynamic and organic factors in human behavior. The strong feelings of counter-transference often provoked by working with mentally retarded patients permits the trainee to identify and come to grips with the regressive forces within himself in the early stage of his career, thus increasing his general therapeutic effectiveness.

The psychiatrist's role as an interdisciplinary coordinator, currently emphasized in psychiatric training, seems especially applicable to the field of mental retardation. The complexity of the problem calls for cooperation of many medical and nonmedical specialties. His knowledge of group dynamics and training in recognition of and dealing with the interaction of social, biological, and psychological factors places the interested psychiatrist on at least a par with the other candidates for leadership in many areas of service and community planning. Furthermore, as an expert in human personality development, he should play an important role in the training and education of physicians, psychologists, social workers, and educators in the field of mental retardation. His clarification of the sometimes bizarre behavior of the mentally retarded and the intrafamily tensions provoked by a retarded family member will greatly increase the effectiveness of all disciplines.

The role of volunteers in the field of mental health and mental retardation is of great practical importance in view of the acute shortage of trained personnel. Psychiatric guidance and supervision may increase the volunteers' competence and permit maximal utilization of their services, particularly in the process of social rehabilitation.

The reasons behind the institutionalization of the majority of the retarded are the behavior and attitudes that make it difficult or impossible for the individual to function in the community. The retarded child has as much right to have help with such personality disturbances as his brighter brothers and sisters. Thus, the psychiatrist has an obligation to be equally available to the retarded child and adult.

Role of physicians in other countries. All the pioneers in the beginning of the 19th century came from within the medical profession. They provided the leadership in medical matters of diagnosis and treatment and laid the foundation for the educational and training endeavors as well. The end of the 19th and the early part of the 20th century witnessed a gradual withdrawal of interest in the problem of mental retardation on the part of physicians. Diagnostic and therapeutic nihilism replaced the enthusiasm of people like Itard, Howe, and Séguin.

Medical research came virtually to a standstill, with only a few notable exceptions. The isolation of the mentally retarded both from the community and from the mainstream of academic learning deterred most physicians from personal involvement. It was left to psychologists and educators to pick up the slack and to make the major contributions to the understanding and the management of mental retardation. This phenomenon was more pronounced in the United States than in Europe.

A renewed medical interest in mental retardation in Western Europe and the U.S.S.R. began in the 1930's and has continued with increased vigor since the end of World War II. In the U.S.S.R., psychiatrists and neurophysiologists provide the leadership in research and in practical management, in close collaboration with the fields of psychology and education. In Western Europe, the impact of post-war social psychiatry led to experimentation with new concepts of community-based facilities for the mentally retarded. Most of the modern facilities that now serve as models for planners in this country are directed by physicians who usually come from the ranks of pediatrics and child psychiatry. Although nobody in Europe denies the necessity of interdisciplinary cooperation in this complex area, the physician is generally regarded as the one best suited to guide and coordinate such efforts. The excellence of many existing programs in Europe attests to the wisdom of this approach.

Needs of the Future

Educational programs for medical students and postgraduate trainees. The recent public interest in mental retardation will be followed by a gradually increasing involvement of the entire medical profession, which will be called on to assume leadership and responsibility in providing maximal help to the mentally retarded. The response to this call will depend largely on the development and expansion of training facilities in mental retardation for medical students and residents. The training programs have to be balanced between the theoretical and the practical aspects of the problem and will require a university-based or -affiliated clinical facility for the mentally retarded.

The training of medical students may be regarded as the most essential step in the process of physicians' education in mental retardation. The theoretical training should include human development, biochemistry, genetics, and social aspects of mental retardation. The student should also become acquainted with the problems of community resources and planning, with emphasis on prevention. The practical training is best done in a diagnostic and treatment clinic or in a residential facility that provides opportunity for observation and participation in medical management, parent counseling, contact with other such disciplines as psychology and social work, and some interaction with

public agencies. In addition to this basic, mandatory program, selected students should be encouraged to explore the field of mental retardation in greater depth, through participation in research projects and prolonged clerkship in a clinical setting.

Education in mental retardation must continue in postgraduate programs on several levels. Certain disciplines, such as pediatrics, psychiatry, obstetrics, and neurology, are most involved in the diagnosis, treatment, and prevention of mental retardation. Pediatricians are most strategically situated to detect and combat mental retardation. It is essential, however, to impart some fundamental knowledge of the problem to all physicians, especially to future general practitioners, the "primary" physicians. Such knowledge about mental retardation may be obtained during internship and residency programs and in postgraduate courses and is best provided by addition of specialists in mental retardation to the hospital staffs.

One may predict an increased need of physicians capable of assuming leadership in the field of mental retardation. This need becomes more apparent as the state plans for comprehensive mental retardation programs are emerging. Future leaders will best be recruited from pediatrics, psychiatry, and neurology. Their intensive training should cover the entire spectrum of problems relevant to mental retardation, such as diagnosis and treatment, placement, administration, research, and community relations. It is to be hoped that a variety of such programs will be developed to provide a cadre of versatile specialists, capable of meeting the different needs in this rapidly expanding field.

Community planning. The diversity of the handicaps associated with mental retardation requires a variety of services to meet all needs. They must include diagnosis, treatment, training, recreation, rehabilitation, and protective supervision, and they require a combination of medical specialties, social work, special education, and vocational training. These broad areas of service may be provided by private physicians and agencies, various state facilities and university clinics, public and private schools and hospitals. At present, there is an acute shortage of such services, but as various programs emerge, waste and duplication can be best prevented by careful community planning. The planning body should use existing facilities and support the creation of new ones. It should also pay attention to the training of professional personnel, without which not even the most modern facility can operate.

Recently, the concept of a comprehensive multi-purpose center has gained in popularity. Such centers constitute a fixed referral point in the community. Here, a thorough evaluation and treatment of the entire range of problems is provided, and there is also the most suitable place for parent counseling, with emphasis on proper placement. Such a facility could

cover a defined geographic area, and its usefulness might be increased by strategic location of satellite clinics in its vicinity. In such centers, a risk registry of high risk children would permit early identification of mentally retarded individuals in the area and an early start of treatment if available.

The recognition of the need for coordination of community services has brought forth the concept of "life planner." Such an individual would be intimately acquainted with the contribution of different progressions relevant to the field of mental retardation. His background and skills would enable him to provide life consultation and guidance to the retarded person and his family.

Areas of future research. The present research effort will no doubt become intensified with the establishment of university-based multidisciplinary research centers throughout the country. Several avenues of such future efforts are listed below.

Biochemical research. The inborn errors of metabolism will continue to present a most challenging field. In addition to the recognition of specific blocks of metabolism processes, the interplay between enzymes and the problem of cellular metabolism still await elucidation. The parallel discoveries in chromosomal and enzymatic research may permit the mapping of chromosomes. A breakthrough in the understanding of storage diseases seems imminent. Better understanding of brain metabolism represents another fruitful area, as does the elucidation of the structure of chromosomes.

Other organic factors. There is a pressing need for a better understanding of fetal metabolism and the placental function. The effects of the normal and abnormal birth process on the brain of the newborn and the role of maternal viral disease during pregnancy need to be elucidated further.

Educational research. Basic and applied research will be required to improve present teaching methods. Better knowledge of cognitive processes, application of motivational research, and emphasis on practical life adjustment may bring about radical changes in special education. Introduction of new testing methods may permit a better assessment of the student's strengths and weaknesses. This will obviate the present global approach and would permit the tailoring of individual curricula. The study of language development of the mentally retarded needs urgent attention.

Psychiatric and neuropsychiatric research. Correlation of organic factors with the mental status and personality development represents an area likely to be shared by psychiatry and neurology. Longitudinal personality studies of mentally retarded children will permit better planning for prevention of emotional difficulties and may contribute to a better understanding of early infantile autism and other childhood psychoses.

Suggested Cross References

Some of the specific syndromes associated with mental retardation are discussed in different contexts in Section 2.1 on genetics, in Chapter 10 on neurology, in Section 42.3 on childhood organic brain disorders, and in Section 21.1 on epilepsy. The section on genetics also contains a more detailed discussion of inheritance and of chromosomal aberrations and genetic counseling. Information regarding fundamental neurobiochemical and neurophysiological concepts may be found in Sections 2.2 and 2.5 through 2.9, respectively, in Area B, on the basic behavioral sciences. In that same area there are three sections that deal with social-familial determinants of behavior and intelligence: Section 4.3 on the family and psychiatry, Section 4.2 on sociology and psychiatry, and Section 4.1 on anthropology and psychiatry. Section 3.2 on cognition contains more detailed information regarding the nature and determinants of intelligence. More detailed information regarding the use of psychological tests in the assessment of mental retardation may be found in Section 39.3 on the psychological testing of children and in Section 12.1 on testing of intelligence and personality.

Chapter 23

Psychoneurotic Disorders. I: Anxiety, Conversion, Dissociative, and Phobic Reactions

23.1 ANXIETY REACTION

HAROLD I. LIEF, M.D.

The American Psychiatric Association's *Diagnostic and Statistical Manual, Mental Disorders* defines anxiety reaction as follows:

In this kind of reaction [anxiety] the anxiety is diffuse and not restricted to definite situations or objects, as in the case of phobic reactions. It is not controlled by any specific psychological defense mechanism as in other psychoneurotic reactions. This reaction is characterized by anxious expectation and frequently associated with somatic symptomatology. The condition is to be differentiated from normal apprehensiveness or fear. The term is synonymous with the former term 'anxiety state.'

Anxiety

W. H. Auden has called our era "the age of anxiety." Whether there is, indeed, much more anxiety now than in previous periods is impossible to state with certainty. Realistic threats or stresses have been plentiful in past times: starvation, disease, war, slavery, and natural disasters were ubiquitous and, in many places, still are today. Yet the complexity of civilization, the rapidity of change, and the partial relinquishment of religious and familial beliefs and values are creating conflicts and anxieties less frequent in the more rigidly organized, hierarchical societies of the past.

In any case, much more attention is now being paid to the amount, type, and effects of anxiety, as reflected in current medical practice. Indeed, anxiety has become the cornerstone of both psychosomatic medicine and psychiatric theory and practice. Disordered psychological function is ultimately laid at the doorstep of anxiety in almost every clinical disturbance in the psychiatric textbook, with the possible exception of

sociopathic personality disturbances and disorders secondary to structural damage of the brain. Even in patients with structural damage, anxiety due to feelings of incompetence, inadequacy, and helplessness is a prominent feature of the disturbance.

Definitions. Anxiety is a diffuse, highly unpleasant, often vague feeling of apprehension, accompanied by one or more bodily sensations that characteristically recur for the same person, for example, an empty feeling in the pit of the stomach, tightness in the chest, pounding heart, perspiration, headache, or the sudden urge to void. Restlessness and a desire to move around are also common.

Anxiety is an alerting signal; it warns of impending danger and enables the person to take measures to deal with a threat. Fear, a similar alerting signal, is ordinarily differentiated from anxiety on the basis of whether the threat is known or unknown, external or internal, immediate or future, definite or vague, non-conflictual or conflictual in origin.

This distinction arose by accident. The early translators of Freud mistranslated *angst*, the German word for fear, as anxiety. As Rado pointed out, Freud himself generally ignored the distinction between fear and anxiety. On psychological grounds, evidence seems adequate to ignore the usual distinction that anxiety is associated with a repressed, unconscious object, whereas fear is related to a known, external object. Clearly, fear may also be due to an unconscious, repressed, internal object displaced to another "thing" in the external world. For example, a boy may be afraid of dogs because he is actually afraid of his father and unconsciously associates his father with dogs, or he may be vaguely apprehensive about leaving his home because he has experienced sexual excitement while witnessing dogs mating in the street and now unconsciously links dogs with his guilt-laden sexual feelings.

Psychological features of anxiety and fear. Although fear and anxiety may be indistinguishable

in terms of unconscious psychodynamics (mental mechanisms or psychological forces), the distinction has been made so often in psychiatric publications that it will be observed in this section (see Table I). The separation of fear and anxiety, moreover, is psychologically justifiable, even if not on the usual grounds. (The emotion caused by a car rapidly approaching you as you cross a street differs from the vague discomfort you may experience when you meet new people in a strange setting. The main psychological difference between these two emotional responses lies in their acuteness or chronicity; Darwin maintained that the word "fear" is derived from what is sudden and dangerous. Duration also seems to be vital in the neurophysiological phenomena of anxiety and fear.)

Neurophysiological characteristics of anxiety and fear. Physiological evidence for the separation of anxiety and fear has been assembled by Gellhorn. (Acute fear is accompanied by a decrease in blood pressure, heart rate, and tone in striated muscles and may cause fainting. These signs are associated with a preponderance of vagal parasympathetic or trophotropic activity. Psychologically, the person is overwhelmed by passivity and helplessness. Darwin gives this psychophysiological description of acute fear merging into terror:

Fear is often preceded by astonishment, and is so far akin to it, that both lead to the senses of sight and hearing being instantly aroused. In both cases the eyes and mouth are widely opened, and the eyebrows raised. The frightened man at first stands like a statue motionless and breathless, or crouches down as if instinctively to escape observation.

The heart beats quickly and violently, so that it palpitates or knocks against the ribs; but it is very doubtful whether it then works more efficiently than usual, so as to send a greater supply of blood to all parts of the body; for the skin instantly becomes pale, as during incipient faintness. This paleness of the surface, however, is probably in large part, or exclusively, due to the vaso-motor centre being affected in such a manner as to cause the contraction of the small arteries of the skin. That the skin is much affected under the sense of great fear, we see in the marvellous and inexplicable manner in which perspiration immediately exudes from it. This exudation is all the more remarkable, as the surface is then cold, and hence the term a cold sweat; whereas, the sudorific glands are properly excited into action when the surface is heated. The hairs also on the skin stand erect; and the superficial muscles shiver. In connection with the disturbed action of the heart, the breathing is hurried. The salivary glands act imperfectly; the mouth becomes dry, and is often opened and shut. I have also noticed that under slight fear there is a strong tendency

to yawn. One of the best-marked symptoms is the trembling of all the muscles of the body; and this is often first seen in the lips. From this cause, and from the dryness of the mouth, the voice becomes husky or indistinct, or may altogether fail....

As fear increases into an agony of terror, we behold, as under all violent emotions, diversified results. The heart beats wildly, or may fail to act and faintness ensue; there is a deathlike pallor; the breathing is labored; the wings of the nostrils are widely dilated; 'there is a gasping and convulsive motion of the lips, a tremor on the hollow cheek, a gulping and catching of the throat'; the uncovered and protruding eyeballs are fixed on the object of terror; or they may roll restlessly from side to side.... The pupils are said to be enormously dilated. All the muscles of the body may become rigid, or may be thrown into convulsive movements. The hands are alternately clenched and opened, often with a twitching movement. The arms may be protruded, as if to avert some dreadful danger, or may be thrown wildly over the head.... In other cases there is a sudden and uncontrollable tendency to headlong flight; and so strong is this, that the boldest soldiers may be seized with a sudden panic.

In contrast to anger, in which secretion of noradrenaline increases, fear is accompanied by increased secretion of adrenaline. In acute fear, this increase is insufficient to counterbalance the parasympathetic effect. In a stressful experimental or real life situation—such as riding in an airplane or viewing an emotionally charged movie, in which the person makes no attempt to escape—excretion of adrenaline increases, with little change in excretion of noradrenaline. During interviews before the hospital staff, psychiatric patients excrete more adrenaline but not noradrenaline, provided they remain passively compliant. In acute fear, discharge of the entire autonomic nervous system is probably followed by a dominant parasympathetic-cholinergic (trophotropic) response and then a secondary sympathetic-adrenergic (ergotropic) reaction.

Fear of this profound nature is not often seen clinically. More commonly, the fear is less acute, and a shift to the sympathetic side of the balance in the hypothalamic system occurs and may produce such symptoms as sweating, tachycardia, pupillary dilation, and perhaps tremor due to increasing muscle tone. The balance may also shift in adrenaline-noradrenaline output.

According to Gellhorn, the chronic state of fear or anxiety is associated with a "tuning" of the ergotropic system in response to repeated alerting stimuli that successively lower the threshold for new stimuli; the heightened ergotropic system then dominates the trophotropic system, and blood pressure rises and heart rate increases (palpitation).

Individual patterns of anxiety vary widely. Some patients have cardiovascular symptoms, such as palpitation and sweating; some have gastrointestinal symptoms, such as nausea, vomiting, feeling of emptiness, butterflies in the stomach, gas pains, or even diarrhea; some have urinary frequency; and some have shallow breathing and tightness in the chest. All of these are visceral reactions. However, in some patients, muscle tension prevails, and they complain

TABLE I
Psychological Features of Anxiety and Fear

Duration.....	Chronic	Acute

of muscle tightness or of spasm, headache, and wry neck. The decreased sympathetic activity that follows a decrease in muscle tension is the physiological basis for prescribing muscle relaxation drugs or techniques in anxious patients.

In acute fear, the parasympathetic or trophotropic reactions are the dominant clinical manifestations. In anxiety, sensitivity and responsiveness of both sides of the autonomic neuroendocrine system are simultaneously heightened, and the clinical manifestations depend on the individual pattern of anxiety. Each patient has his idiosyncratic expression of anxiety; once the observant physician detects the pattern, he can recognize characteristic visceral symptoms and minute changes in vascular response and muscle tone.

Since chronic anxiety and anger increase ergotropic reactivity and secretion of noradrenaline, what is the relation of these? According to Gellhorn, "Chronic anxiety... is due to the simultaneous activation of the ergotropic and trophotropic systems at a high level of arousal or psychologically speaking to fear and aggression." Anxiety, then, is a chronic feeling of discomfort due to repeated stimuli that tune up the ergotropic autonomic nervous system and create an excessive discharge in the visceral and motor systems. The motor system, by proprioceptive feedback, accentuates the heightened sensitivity of the ergotropic system.

Stress and anxiety. The stimuli that trigger the chronic state of anxiety are referred to as stresses, but Selye noted that a careful distinction must be made between the external event or internal drive and the organismic response to the stress, since these are occasionally confused. The term "stress" should be reserved for the stimulus that triggers the excessive autonomic reactions described. An external event, then, such as loss of a job, or an internal drive, such as the desire to punch the boss in the nose, can be called a stress only if the patient is unable to cope with it, only if the nervous reactivity is excessive or prolonged.

Whether an event is stressful or not, then, depends on the nature of the event as well as on the resources, the defenses, and the coping mechanisms of the person. These all involve the ego, a collective abstraction that refers to the processes by which a person perceives, thinks, and acts on external events or internal drives. If his ego is functioning properly, he will be in adaptive balance with both his external and internal worlds; if it is not functioning properly and the imbalance continues long enough, he will develop chronic anxiety. The time required to establish a psychoneurosis varies widely among human beings.

Whether the imbalance is between the pressures of the outside world and those of the patient's ego or is internal, between his impulses (aggressive, sexual, or dependent) and his conscience, the imbalance produces a conflict. Conflicts caused by external events are usually termed interpersonal, whereas those caused by

internal events are called intrapsychic. Of course, a combination of the two is possible, as in the case of the underling who has an excessively demanding or critical boss and who must control his impulse to bash the boss on the head for fear of losing his job. Interpersonal and intrapsychic conflicts are, in fact, usually combined, since human beings are social animals and their main conflicts, despite their inner representations, are with other people.

Conflict seems to be another essential ingredient of anxiety, although its absence is not a requisite for fear, since conflict is present in a special type of fear called phobia. In the genesis of experimental neurosis, conflict is an essential ingredient, as when sexual arousal is prevented or interfered with so that a strong excitation cannot be discharged or when an attack of rage is not executed because of inhibition of movement.

The cause of chronic anxiety can be summarized in the following way. Repeated attacks of fear—or a single attack in exceptional cases, as in persons with a traumatic neurosis or in those with certain phobias—provide the chronic stress to produce intense and long lasting autonomic neuroendocrine reactivity, accompanied at the psychological level by conflict. This pattern results in chronic anxiety.

Levels of anxiety. Like all emotions, anxiety exists at three levels. In ascending order, there is a neuroendocrine level, a motor-visceral level, and, finally, a level of conscious awareness. Generally, the person is conscious of only a disagreeable feeling and more rarely of intense discomfort, but he is usually not aware of the cause of his anxiety.

The disagreeable feeling has two components: (1) the awareness of the physiological sensations (palpitation, sweating, butterflies in the stomach, tightness in the chest, shaking knees, quavering voice), and (2) the realization of being nervous or frightened. The anxiety may be increased by a feeling of shame—"Others will recognize that I am frightened." Many patients are astonished to find that others are not cognizant of their anxiety, or, if they are, do not know the intensity of the patient's sensations.

In addition to the motor and visceral effects of anxiety, the important effects on thinking, perception, and learning should not be overlooked. The brain is a central integrating mechanism, but it is also an end organ. Anxiety tends to produce confusion and distortions of perception, not only of time and space but of people and the meaning of events. These distortions can interfere with learning by lowering concentration, reducing recall, and decreasing ability to relate one item to another (association).

An important aspect of emotional thinking, including anxious or fearful thinking, is its selectivity. Under the influence of anxiety, a person is apt to select certain items in his environment and overlook others, all in the direction either of falsely proving that he was justified in considering the situation frightening and

in responding accordingly or, conversely, of seeking reasons for false self-reassurance that his anxiety was misplaced and unnecessary. If he falsely justifies his fear, his anxieties will be augmented by the selective response, setting up a vicious circle of anxiety—distorted perception—increased anxiety. If, on the other hand, he falsely reassures himself by selective thinking, appropriate anxieties may be reduced, and he may then fail to take the necessary precautions.

Selective perception and thinking may affect not only the inclusion and the exclusion of events, people, and things, but also the meaning of words and actions. It may thus become an instrumental factor in prejudice, which, *a priori*, determines the meaning of an event before it happens or stereotypically assigns a person or action to a certain class or group on the basis of a shared attribute, often irrelevant to the action that is the focus of attention.

Adaptive functions of anxiety. As an alerting signal, anxiety can be considered as basically the same emotion as fear. It warns of a threat, external or internal; it is probably life-saving more than once in a lifetime. At a lower level, it warns of threats of bodily damage, pain, helplessness, possible punishment, or frustration of social or bodily needs; of separation from loved ones; of a menace to one's success or status; and ultimately of threats to one's unity or wholeness. In this way it prompts the necessary steps to prevent the threat or at least to lessen its consequences. A few examples of warding off threats in daily life include getting down to the hard work of preparing for an examination; dodging a ball thrown at one's head; sneaking into the dormitory after curfew to prevent punishment; running to catch the last commuter's train; rehearsing a speech before many or one (boss, girl friend). Anxiety prevents damage by alerting the person to carry out certain acts that forestall the danger.

Since it is clearly to one's advantage to respond with anxiety in certain threatening situations, we can speak of normal anxiety in contrast to abnormal or pathological anxiety. Anxiety is normal for the infant who is threatened by separation from parents or by loss of love, for the child on his 1st day in school, for the adolescent on his first date, for the adult when he contemplates old age and death, for anyone who is faced with illness. Anxiety is a normal accompaniment of growth, of change, of experiencing something new and untried, of finding one's own identities and meaning in life.

Pathological anxiety, on the other hand, is an inappropriate response to a given stimulus by virtue of either its intensity or its duration. Sometimes the physician may not be certain whether a given anxiety reaction is appropriate, but in patients with chronic anxiety, such reactions are usually inappropriate.

An interesting phenomenon is the courage displayed in a real emergency by a patient who responds to trivial stimuli with intense fear. A woman patient with

almost daily anxiety attacks, for example, calmly and skillfully dealt with a holdup of a finance company she managed and was astonished when she was shown the discrepancy between her anxiety responses in handling servants, dog, and neighbors and her lack of anxiety during the holdup.

In this sense, anxiety can be compared with another alerting signal—pain. A few persons with congenital absence of the sensation of pain have been studied. Although they do not fear visits to the dentist, they cannot seem to prevent getting all sorts of cuts and burns; they even manage to eat their tongues. In the absence of pain, they are ill prepared to identify their infections or to take the necessary precautions when ill.

Substitute anxiety for pain, and imagine a person with congenital absence of the sense of anxiety. How long would he survive? In contrast to pain, anxiety is a signal that warns of distant or future threats to the entire organism, rather than of nearby or immediate threats to specific sites of the body.

Of the two alerting signals, pain is generally withstood better than anxiety. The ability to tolerate anxiety varies widely. Indeed, this ability may be an essential factor in differentiating the normal from the neurotic person, for the neurotic has great difficulty coping with anxiety appropriately. During combat, however, many soldiers who had had only slight anxiety in civilian life succumbed to stress under battle earlier than neurotic soldiers to whom anxiety was not strange. Experience with anxiety can thus be helpful in coping with new situations, but it may also increase vulnerability to stress. Among other things, this variability indicates the complexity of ego processes and the difficulty of making rigid rules about human behavior.

Anxiety usually leads to action designed to remove or reduce the threat. This action can be constructive, in which case one can speak of coping mechanisms if the action is largely a conscious, deliberately selected one (such as studying for an examination) or of defense mechanisms if behavior is largely determined by unconscious forces (such as repressing or burying a threatening impulse or idea, pushing it out of awareness).

A mechanism of defense can be adaptive or non-adaptive, depending on the consequences. Repression is used many times in the course of a person's life to achieve harmony with his environment and within himself. Only if symptoms of pathological behavior result can repression or any other mechanism of defense be considered abnormal.

The need to rid oneself of this painful and disagreeable emotion is so great that a person may resort to a variety of devices designed to repair the situation. All too often, these reparative devices miscarry and result in self-damaging behavior. They may overshoot the mark, just as an inflammatory reaction that develops to wall off an abscess may destroy tissue or

impair function or just as fever designed to destroy bacteria may rise too high and destroy the patient. Sometimes the "repair" exacts too high a price in reducing function or pleasure. Examples of miscarriages of organized reparative attempts at limiting or reducing anxiety are phobic, depressive, compulsive, hysterical, conversion, dissociative, and inhibited patterns of behavior.

In many instances anxiety is not bound by these attempts at repair, and it breaks through and combines with phobic, compulsive, hysterical, or other psychoneurotic patterns to create mixed psychoneurotic reactions. When attacks of anxiety are the most prominent clinical feature, however, it is proper to speak of an anxiety reaction. Occasionally, anxiety reactions are almost pure, without any admixture of psychosomatic, compulsive, or hysterical symptoms. A combination of pathological responses, however, is far more common.

Anxiety Reaction

Anxiety reaction, the official terminology of the American Psychiatric Association, has now replaced "anxiety state," which, in turn, had replaced the even older "anxiety neurosis." Freud used "anxiety neurosis" in 1894 to describe a syndrome characterized by general irritability, anxious expectation, anxiety attacks, somatic equivalents of anxiety, and nightmares. He made a distinction between "actual neurosis," to signify the tense irritability and anxiety due to failure of physiological discharge of sexual tension, as in coitus interruptus, and "anxiety hysteria," comprising phobias, conversion symptoms, and other hysterical manifestations as well as anxiety based on a psychic "dammed up libido." In 1926, Freud finally recognized that anxiety could be caused by conflicts over nonsexual as well as sexual drives and hypothesized that anxiety is the cause of repression rather than its consequence. In any case, anxiety was separated from hysteria as the term "anxiety hysteria" was abandoned and in the United States was eventually replaced by "anxiety reaction." However, in some European psychiatric textbooks, anxiety neurosis is still used, while anxiety reaction is used in others.

Epidemiology. It is extremely difficult to determine the incidence (the number of new cases during a unit of time) of any psychiatric illness. It is almost impossible to determine precisely *when* new cases appear; even first admissions to hospitals may tell nothing of the earlier history of patients. In the case of an entity such as anxiety reaction, for which hospitalization is rarely required, the number of first admissions as an index of incidence is clearly impractical. Nor can the number of out-patient admissions be used, since there is no way of knowing how many persons with the same syndrome do not seek help or go to nonpsychiatrists or paramedical professional persons for help. It is even difficult to collect adequate statistics from psychiatrists in private practice, although recent

attempts in one county have been made to establish a county-wide, uniform registry of psychiatric patients. The problem is complicated by the varying criteria for diagnosing anxiety reaction in different psychiatric centers. What may be called anxiety reaction in one center may be termed schizophrenic reaction in another.

Because of these difficulties, most epidemiological studies have been designed to measure the prevalence (total number of cases in a given population at a given time) of a given psychiatric disorder. Even though it is easier to measure prevalence than incidence, this approach has serious obstacles as well. The standard nomenclature classifies full blown pathological disorders, not milder emotional disturbances. By questionnaire or interview, the investigator collects symptoms and can, therefore, describe only patterns of symptoms. Most studies categorize a person by groups of symptoms that correspond only roughly to the standard classifications; and then they grade the severity of symptoms. The finding by Hollingshead and Redlich that the incidence of neurosis is higher among persons in the upper classes than among those in the lower classes and that the opposite relation is true for psychosis has been widely disseminated. A more recent study of other communities by Leighton et al., on the other hand, indicated greater prevalence of psychophysiological and psychoneurotic symptoms among the lower than the upper classes. In at least a third of the population, these chronic, mildly impairing disturbances create problems that require alleviation and prevention. Since anxiety reactions constitute a high percentage of psychoneuroses and since most psychophysiological symptoms are expressions of anxiety reactions, a significant segment of the community, perhaps one fourth, has anxiety reactions severe enough to warrant professional aid.

Leighton et al. contended that "if the entire population of Stirling County [a rural community in Nova Scotia] were studied intensively by competent psychiatrists, approximately two-thirds would be found to have been suffering at some time during their lives from a psychiatric disorder (for the most part, low-grade and chronic) according to the criteria of the APA Manual" and that "at least half the adults [in Stirling County] are *currently* suffering from some psychiatric disorder." The Midtown study by Srole et al. reported that only 2 out of every 10 adults had been untouched by some psychiatric disability. In the Stirling County study, three variables were important in determining variation in distribution of psychiatric disorders: sex, age, and disintegration of the sociocultural system, all of which are of importance in etiology.

Etiology

Historical aspects. Understanding of the multiple complex factors in the development of an anxiety reaction is obscured by failure of most authors to

distinguish among acute anxiety, chronic anxiety, and anxiety reaction. Psychiatric publications contain extensive discussions of the cause of anxiety, but much less frequently discussions of the anxiety reaction syndrome.

Mistranslation of Freud's word for fear, *angst*, popularized the term anxiety. Freud radically changed his early views about the origins of anxiety, and his later formulation still dominates current thinking. He regarded anxiety as the cause of repression, a mechanism that wards off "instinctual" (a term only loosely related to a biologist's concept of instinct) drives that threaten the individual with loss of love or symbolic castration. These drives are usually incompletely repressed and, as they reach consciousness, evoke anxiety.

Rank popularized the concept of "birth trauma," now known as "separation anxiety" or anxiety over the fantasied separation from one's mother. Freud regarded the flooding of the organism by stimuli during birth as the prototype of anxiety later in life, for anxiety is characterized by excessive bombardment by stimuli of the nervous system, which then hyperreacts. In this sense, the birth experience, despite the absence of self-awareness, may lay the groundwork physiologically for later anxiety experiences.

Sullivan stressed the relation of the genesis of anxiety to the emotional bond between mother and child, especially until the child is 27 months old. The anxiety of the mother is transmitted, perhaps proprioceptively, to the child, who in turn transmits his anxiety back to the mother—a vicious circle or, in communication terms, a positive feedback. Sullivan regarded anxiety as essentially a fear of mother's disapproval because of a threat to this empathic bond between mother and infant. Anxiety occurs whenever a child senses his mother's disapproval, since he learns that his comfort or discomfort is dependent on whether his mother is loving and nonanxious ("good") or nonloving and anxious ("bad").

Adler regarded anxiety as the apprehension of the threat to a person's life style, whereas Horney regarded it as a consequence of a threat to an individual's self-image. Horney and others stressed conflict as the source of anxiety—a conflict, for example, between dependency needs and hostile impulses toward a parent. Masserman, along with Fromm, stressed man's existential anxieties—fear of death, of physical damage, of loneliness, and of relative insignificance. Masserman pointed out that, in the development of experimental neuroses, conflict need not be based on fear; positive but mutually exclusive goal-seeking patterns may be almost as significant in the production of behavioral disturbances as conflicts based on fear.

Horney took a much more optimistic view of the child's development than did Freud; she argued that the child has potentials for growth and self-realization and is not constantly trying to subdue his evil impulses, as Freud had suggested. Both Horney and

Freud considered the anxiety created by stress or danger to be related to the maturational level of the child. In the beginning, when the child is biologically and psychologically most helpless and dependent, the danger is the loss of the person on whom he depends. Later the danger is the loss of that person's love. Still later it is castration anxiety, followed during latency by the fear of punishment (guilt), and eventually by the fear of not living up to one's own expectations (shame). Horney placed special emphasis on shame anxiety.

Rado regarded fear and anxiety as synonymous terms. The infant is born with certain emergency emotional equipment, including fear and rage. The prototype of the fear reaction is the startle response when the child's nervous system is overwhelmed by excessive stimuli. Rado traced the development of emergency emotions in increasing complexity, emphasizing the effect of the development of conscience on guilty fear, the most important of the emergency emotions. In his view, guilty fear is the primary cause of most behavioral dysfunctions. The constitutional readiness for an emergency response is strikingly demonstrated by the experimental proof that the fetus can be conditioned during the last 2 months of gestation. From these experiments, it is clear that the psychophysiological state of the mother may exert a significant influence on the behavioral pattern of the normal fetus.

A contemporary formulation. The basic etiological feature of almost all psychoneurotic reactions is a disturbed parent-child relationship. The emergency emotions of fear and rage are built into the organism genetically. Frustration of the child's needs for love, food, warmth, exploration, and motility cause him to respond with his emergency equipment—fear and rage. At first, this is expressed in an undifferentiated cry for help; later, cries of pain, fear, rage, and, still later, wounded pride can be distinguished by a sensitive mother.

The dependency of the human infant on his mother for survival and gratifications is longer than that of any other animal. The sense of helplessness that this engenders becomes a potent factor in the anxiety reaction of adult life. The adult faced with tasks or situations that seem insurmountable revives the frightening sense of helplessness, which creates more anxiety, in a circular phenomenon.

The infant's absolute dependency upon his mother makes their relation the most critical factor in the development of psychopathological disorders. The harsh, unloving mother, the overprotective mother, and the mother who confuses her child by incompatible signals stir up excessive anxiety. The reservoir of anxiety, the heightened vulnerability to stress, and the types of miscarried reparative defenses used determine, in large measure, the person's type of psychopathological disorder and the degree of maladaptation and impairment of function later in life.

Some anxiety is normal and presumably necessary for growth, for every step forward is accompanied by anxiety. In this context, anxiety serves to initiate change, to augment curiosity, to push the child in the direction of mastery of himself, his body, and his environment. Whiting concluded from evidence collected from various cultures around the world that some emotional deprivation accompanied by anxiety is necessary for ego development. In anxiety reaction, however, anxiety is no longer a positive force; rather, it becomes the damage that the person is trying to avoid. The change from a constructive to a destructive force is largely the result of malignant influences in child rearing.

The most important of all these influences, psychodynamically, is the excessive and distorted development of conscience. The child's ideas of right and wrong develop through countless interactions with his mother and other parental figures. A warm smile, a kiss, a pat, kind words indicate approval and reinforcement of the child's behavior, whereas a raised eyebrow, a frown, slightly increased vocal pitch, or the more severe storm of abuse or spanking indicate disapproval and repudiation of the provoking behavior. Overemphasis on disapproval and punishment, especially when coupled with excessively high expectations on the part of the parent, gradually develops a strict, overscrupulous, perhaps even harsh conscience in the child. The alerting signal that evokes unrealistic self-condemnation is guilty fear or guilty anxiety—the automatic feeling that “I have done something wrong; punishment is inescapable.”

Of all the sources of anxiety, the most prominent clinically is guilt. Since the expectation of punishment is a part of the emotion, anxiety normally accompanies guilt. If the feeling of wrongdoing is accompanied instead only by fear of detection, the conscience is not fully developed and sociopathic traits, without much anxiety, result. The child with too strict a conscience becomes frightened of sexual and aggressive (even normal self-assertive) impulses because of the fear of punishment, the ultimate of which is abandonment. The stage is then set for later attacks of anxiety in interpersonal situations in which self-assertion is needed or in which rage or sexual demands become too intense. Repression and dissociation of drives that may provoke retaliation lead to smoldering resentment and to crippling of affectionate or affiliative impulses, for these are also perceived as dangerous. Tensions build up, the nervous system is excessively stimulated, and some of the somatic disturbances already mentioned may appear.

The most significant and specific affiliative drive resulting in guilty anxiety is the one directed toward the parent of the opposite sex. In all likelihood, the oedipal drive is not simply an instinctive drive but is at least partly learned, stimulated by the parent of the opposite sex. In any case, the desire for love, affection, and a feeling of security from this parent is often sex-

ualized and becomes guilt-laden, resulting in what Freud called “castration anxiety” but what Rado, perhaps more properly, termed “genital diminution fears.” These fears assume great significance in clinical practice because they are often etiologically related to anxiety attacks. Genital diminution fears are also engendered by parental threats regarding masturbation and sex play with other children and by the child's frequent misinterpretation of sexual intercourse as an act of violence.

In addition to threats that emanate from these disturbed family relations, threats from modern complex society are manifold. The old crutches of religious belief and family solidarity are disappearing, and modern man is left to hobble along, increasingly isolated from the extended family and significant group relations, sources of emotional support and identification in previous generations. In an age of increasing mechanization, automation, and dehumanization, the search for the meaning of existence and the struggle to overcome alienation preoccupies and causes anxiety in many. For some, the quest for power and possessions goes on, often accompanied by a gnawing sense of failure or of guilt over success. Competitive conflicts may be sexualized and may bring, in their wake, anxieties over gender role and sexual performance.

Sex. The prevalence of psychiatric disorders, including anxiety reactions, differs according to sex. Women are more apt to have anxiety reactions than are men, but their level of impairment is only slightly higher than that for men. Anxieties about menstruation, pregnancy, and the menopause are extremely common. In addition, modern society has created role conflicts for women. No longer are they content to be “feeders, breeders, and follow the leaders.” Society assigns different values and symbols to the sexes in their search for recognition, security, sexual satisfaction, love, and expression of hostility. Sociological change may also affect the sexes differently.

Conflicts over roles assigned by society or achieved by individual effort are not restricted to women. The man is still required to be a *man*, whereas his mother and later his wife may, in various ways, try to emasculate him—only to complain later about his passivity and lack of assertion. An anecdote perhaps describes this situation better than a thousand words of scientific analysis could.

In the kingdom of heaven were to be found two gates. Above each gate was a sign. One sign read, “Here enter passive, dependent men.” In front of this sign was a long line that stretched as far as the eye could see. At the other gate was a sign that read, “Here enter self-assertive, masculine men.” In front of this gate was a solitary man—a very slight, somewhat effeminate, passive male who looked like Casper Milquetoast. St. Peter approached him and said, “I'm surprised to see you in front of this gate; why are you here?” The man replied, “My wife told me to come here.”

In a passive, dependent, and compliant man, efforts at self-assertion may provoke anxiety, for he often

fails to differentiate normal self-assertion from aggression motivated by a wish to attack another person. This difficulty in distinguishing between the two—indeed, the frequent inability to distinguish degrees of assertive behavior—has as its basis an unconscious wish to remove or destroy all competitors. The enormity of the unconscious crime results in severe inhibition. This competitive failure is evident not only at work but in a variety of social encounters, particularly in heterosexual behavior. Even abortive efforts at initiating or maintaining contact with women, to gain sexual satisfaction, may engender severe anxiety. Heterosexual failures may cripple masculine pride and, in turn, provoke homosexual panic—which is usually based not, as is popularly thought, on latent homosexual tendencies but on the inappropriate fantasy, “I am not a man; therefore, I must be a woman and will be used as a woman by superior and more powerful men.”

In both sexes conflicts and confusion over gender identity and role may be potent sources of recurrent anxiety attacks.

Age. Anxiety is prevalent in childhood and adolescence. Indeed, it inevitably accompanies growing up. But, even when pathological, it does not usually lead to anxiety reactions in either childhood or adolescence. In childhood, chronic anxiety leads to habit disturbances, such as nail biting, thumb sucking, and enuresis; to disorders in conduct; or to such neurotic traits as tics, habit spasms, and phobias. Anxiety attacks, as such, are less common than in adult life. Common causes of childhood anxiety listed by Meares include threats to dependency on the mothering figure, latent hostility in the mother, disharmony between parents, inconsistent discipline, emotional insecurity in parents, birth of a sibling, minor mental and physical handicaps, unwise punishment, and threat of castration.

In adolescence, anxiety leads either to severe inhibition or to overactivity, infrequently to anxiety reactions. Common causes of adolescent anxiety include feelings of inadequacy in groups and in new social situations; meeting members of the opposite sex; concern over masturbation and nocturnal emissions; fears of genital abnormality or sexual inadequacy; and lack of self-confidence in performance, whether sexual, social, athletic, or intellectual.

Although society's attention has been focused on the damaging consequences of adolescent rebellion (delinquency, truancy, drug addiction, promiscuity), less attention has been paid to the many teen-agers who respond to anxiety with shyness, awkwardness, social withdrawal, and isolation. These reactions are motivated by anxiety, but they do not, in themselves, constitute anxiety reactions.

Generally, as age increases between 20 and 70 years, the chances of having a psychiatric disorder increase. For men there is a plateau between 40 and 60 years and then a sharp increase in incidence of psychiatric illness between 60 and 70 years. Psychiatric disorders

in women increase until 50 years of age and then, as in men, increase again after 60. For both men and women, psychiatric disorders decrease after the age of 70.

The period between 20 and 40 years has been interpreted by Leighton et al. as the period of struggle. Women continue to show anxiety reactions and depression during the menopausal period, up to the age of 50 years. Between 60 and 70 years, people have to come to terms with their failures, old age, and eventual death, and so anxiety and depression again increase during this decade. The decrease in psychiatric disturbance after 70 is due to the ability of most old people to adapt to life and death, to lower their aspirations and strivings, and to tolerate frustration better.

As Erikson said, the young adult has two primary developmental tasks: occupational identification and the capacity for intimacy. Anxiety is a regular accompaniment of the growing capacity to work and to love, but anxiety may be abnormal and result in either anxiety reactions or neurotic syndromes of bound anxiety.

As the young adult grows older, he becomes increasingly occupied with what Erikson has called “generativity versus self-absorption.” Even in productive, creative persons, pathological anxiety may result from inappropriate levels of aspiration and the attempt to achieve impossible goals—what Horney calls the “search for glory.” Persons who consider themselves failures, either because of real lack of generativity or because they have not realized their aspirations, become absorbed in themselves and less concerned with people in the world around them. Their resultant oversusceptibility to environmental stress often leads to depression and anxiety reactions.

In the 6th and 7th decades of life, anxiety is often the result of repressed resentment and rage. The anger is usually directed toward persons on whom the patient is dependent, such as children, siblings, spouse, or employer. The fear of being abandoned, the fear of loneliness, arises in opposition to feelings of rage, and anxiety attacks may supplant the inhibited angry feelings. The continual decrease in effective interaction with the environment, especially in persons with some brain damage, may be extremely frustrating, and small tasks, routine in the past, may create anxiety.

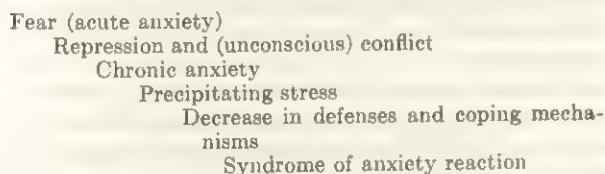

Sociocultural disintegration. The Leighton research team found evidence of a positive correlation between psychoneurotic and psychophysiological symptoms and sociocultural disintegration, but they found no correlation between psychotic symptoms and sociocultural disintegration. Sociocultural disintegration is characterized by high frequency of broken homes, in the sense of the malfunctioning family; few and weak associations in religion, work, and recreation; few and weak community leaders; few patterns of recreation; high frequency of hostility; high frequency of crime

and delinquency; and weak and fragmented network of communications.

The decline of emotional support previously provided by close family ties, together with the complexity of modern living, has made social structure an increasingly important etiological factor in mental illness. A social structure that is psychologically integrated gives support to people in crisis, whereas one that shows evidence of disintegration increases the emotional burdens of people at critical times in their lives. As a result, anxiety reactions, along with the other psychoneuroses, become more prevalent.

Precipitating factors. Some of the chronic factors in the development of anxiety reaction have already been mentioned. Almost invariably, however, there is a single precipitating factor. For this reason, the physician should inquire closely about events immediately preceding development of the attack of anxiety for which the patient is seeking help. Discovery of the conscious and unconscious factors precipitating the last attack of anxiety may help alleviate the patient's discomfort; moreover, the precipitating factors are almost invariably linked psychodynamically to chronic ones, such as repressed rage or the impulse to act out sexually.

In every patient with anxiety reaction, the physician can retrospectively observe the breaking down of defenses and coping mechanisms. Usually this occurs gradually, but sometimes it is an abrupt process related to the precipitating stress. A very common, but probably not invariable, sequence of events leading to anxiety reaction can be illustrated diagrammatically:

In this formulation, fear leads to repression, whereas chronic anxiety results from conflict, all or part of which is usually outside awareness. This is one way of resolving, at a psychodynamic level, the issue of fear versus anxiety, and the psychological explanation of the origin of chronic anxiety remains consistent with the analysis of the physiological differences discussed earlier.

Clinical description

History. The patient with anxiety reaction presents a history of chronic anxiety with acute exacerbations, but this label is an abstraction, an interpretation based on a large variety of symptoms. The chief complaints may be one or more of dozens of symptoms: "I feel tense." "I have trouble falling asleep." "I feel something awful is going to happen to me." "I worry all the time." "I'm afraid to remain alone." "I have bad dreams." "I have palpitations." "When-

ever I'm in a new group, I have butterflies in my stomach." "When I go out on a date, I get nauseated." "I get dizzy and feel I'm going to faint." Although the onset may seem sudden, a careful history will disclose evidences of chronic anxiety. Habit or conduct disturbances in childhood and disturbances in social or group relations in adolescence are extremely common.

General symptoms. Pain may be in any part of the body but is usually described as headache, especially a sensation of a tight band around the head; epigastric pain; or back pain. Giddiness or dizziness may result from hyperventilation; if this symptom is prominent, the patient probably has pins and needles (paresthesias) of the hands and feet. Other symptoms include bizarre feelings in the head, such as swelling or bursting; a sensation of floating in space and other disturbances of the body image and the relation of the body to space; fatigability, seemingly disproportionate to physical exertion; and sweating, especially of the palms, unrelated to high environmental temperature.

In addition, the patient's general attitude reflects helplessness and apprehension. The smallest obstacle may be insurmountable: The next day is the harbinger of death; the next visitor, the bearer of bad news; the next event, the beginning of catastrophe. Overly concerned with what others think of him, the patient is constantly trying to make a favorable impression but is never satisfied with his performance. Uncertain of himself, he may belittle and degrade others in a misguided effort to raise his own self-esteem, all the while castigating himself for his failures. Although the patient with anxiety reaction may exhibit considerable drive, it usually has a compulsive quality and is accompanied by misgivings regarding his competence to perform the task. His activities have a driven quality that robs performance of much of its zest and success of its pleasure.

A sense of tension is almost always pervasive. Unable to relax, the patient may complain of constant restlessness, the inability to sustain any endeavor, even an ostensibly pleasurable pursuit. The tension often interferes with sleep. Difficulty in falling asleep is common, as is fitful sleep accompanied by unpleasant, sometimes terrifying dreams.

Somatic symptoms vary, but each person has his particular combination. As the presenting complaints, they may complicate differential diagnosis. Although anxiety reaction is characterized by chronicity, acute attacks of fear and milder attacks of anxiety may be periodically superimposed on the chronic state of apprehension, overalertness, irritability, tenseness, timidity, uncertainty, and excessive dependency.

Acute anxiety is frequently initiated by symbolic stimuli, which owe their force to the meaning attached to them by the patient. One patient had an intense attack of anxiety on being presented with a picture of her recently deceased husband. A married man had a panic reaction in church the morning after a chance encounter and pleasurable sexual reunion with an old

girl friend. A teen-aged boy had an attack of acute anxiety followed by paralysis of one leg after having seen a movie in which a young man fell from a roof. In general, crowded public places, such as theaters, churches, department stores, and football stadiums, seem to provoke acute anxiety reactions, although panic reactions during sleep or while falling asleep are also common.

Although brief, an acute anxiety attack can be terrifying to the patient. Feelings of impending death or of mental disintegration are common. Understanding the cause of the attack can bring enormous reassurance to the patient.

Motor system. Headache, neck and back pain, easy fatigability, and weakness are common. Tension in any group of muscles may produce tremor and painful movement. Restlessness may be prominent, and clumsiness in making finer movements and an unsteady, quavering voice may be obvious.

Alimentary system. Anorexia, indigestion, nausea, vomiting, distention, flatulence, foul taste in the mouth, constipation, diarrhea, belching, emptiness, or butterflies in the stomach may be noted alone or in various combinations.

Respiratory system. Shortness of breath and constriction in the chest may cause discomfort.

Cardiovascular system. Pain in the chest may be accompanied by palpitations, throbbing sensations, or sensations of heat and flushing of the face.

Genitourinary system. Urinary frequency or urgency may be troublesome. Occasionally, interest in sex decreases, and impotence, menstrual irregularity, and dysfunction may occur.

Central nervous system. Insomnia, lack of concentration, irritability, nightmares, forgetfulness, and hypersensitivity to normal bodily processes (pulse, heart beat) may be serious complaints.

Examination of the patient. The patient with an anxiety reaction is fidgety and restless. He often sits on the edge of his chair. He may twist and turn something in his hands, cross and recross his legs, pull up his socks, rearrange his clothes, light and half-smoke cigarette after cigarette. If a patient is sitting with his legs crossed when discussing a particularly charged topic, his suspended foot may dorsiflex. Similar cues to emotion-laden topics may be flushing of the face or occasionally sudden pallor, sharp intake of breath, twitching of facial muscles around the eyes or mouth, sudden movement of the eyes from right to left, quavering of the voice, or scratching or rubbing movement of the hands. Every person has a telltale way of showing anxiety, and the alert observer should be able to detect the patient's particular signal of distress and then watch for it in subsequent interviews.

The facies and general manner of the patient reflect apprehension, worry, and undue concern. In manner and in words, he may plead for help; he may hang on every word of the doctor or, conversely, be

so preoccupied with his own thoughts and feelings that he pays little attention to the physician.

Anxiety has various effects on speech patterns. Pressure of speech may be manifested by rapid, staccato, machine gun-like quality, but slow, halting speech with episodes of blocking are also common, especially if depression is mixed with anxiety. The patient's conversation may be filled with concerns over bodily functions, hypochondriacal fantasies, thoughts of impending doom, or mental disorganization, or it may be dominated by expressions of helplessness in the face of seeming disaster. He may flit from one subject to another, either from inability to concentrate or from a need to tell the doctor everything at once. Throughout the interview, his face may express the unspoken question, "Can you help me?"

Gross distortions of perception or of thought processes are uncommon in anxiety reaction. When they are present, the physician should think of an agitated depression of psychotic proportions or of schizophrenia.

Physical examination may reveal slight tachycardia, usually not more than 100 beats per minute; rapid breathing; flushed face and neck; moist, cold palms; finger tremor; and brisk tendon reflexes.

Differential diagnosis

Agitated depression. It is important to differentiate anxiety reaction from agitated depression, in which suicidal risk is serious. The patient in whom severe anxiety develops in middle or later life should be suspected of having an agitated involutional psychotic depression. In the absence of paranoid ideation, it may be difficult to make this differential diagnosis, for the patient with an agitated depression may be more agitated than depressed. The physician has to judge the degree of depression, one index of which is the extent of self-depreciation, a cardinal feature of an involutional depression. In depression, the outside world is seen as depriving, the self is viewed as worthless, and the future is hopeless. (In anxiety reaction, the outside world is threatening rather than depriving, the self is judged inadequate rather than worthless, and the future is uncertain rather than completely hopeless.)

Early schizophrenia. Anxiety may be a significant feature of early schizophrenia. Differentiation rests on finding the other symptoms of schizophrenia, such as autism, a previous schizoid life pattern, serious disturbances in perception and thought processes, and excessive ambivalence in interpersonal relations.

Early chronic brain syndrome. Especially in insidious onset of cerebral arteriosclerotic disease, anxiety may be prominent. Anxiety created by increasing failure to carry out tasks, by frustration from ineffective interaction with environment, by threats to security, or by decrease in independent action may become intense. Differentiation is based on the symptoms of chronic brain syndrome, such as loss of recent

memory, impaired judgment, disorientation, especially for time, and the physical signs of arteriosclerosis.

Hyperthyroidism. The most important medical syndrome that symptomatically mimics anxiety reaction is hyperthyroidism. An apprehensive appearance, moist palms, tachycardia with palpitations, and diarrhea may easily be attributed to anxiety. Furthermore, onset of hyperthyroidism is often associated with a stressful life event, such as loss of a family member or loss of a job. A chronically anxious patient may also have elevated systolic blood pressure, a slightly enlarged thyroid, and some lag of the upper lid. When in doubt, the physician should rely on protein-bound iodine-131 measurements.

Other systemic diseases. Anxiety reaction with prominent somatic symptoms may resemble a variety of syndromes. Prominent gastrointestinal symptoms may simulate an early peptic ulcer; cardiovascular symptoms may suggest paroxysmal tachycardia or coronary disease with angina; respiratory symptoms may appear to be due to bronchial asthma; the fatigue of generalized muscle tension may make a physician think of Addison's disease; and the tremulousness of anxiety may even mimic hyperinsulism.

Prognosis. As in other psychiatric disorders, the prognosis in anxiety reaction depends on a set of interrelated factors: the previous personality of the patient, more particularly his ego strength; the acuteness or chronicity of symptoms; the life circumstances of the patient, particularly the nature of stresses impinging on him and the quality of emotional support available to him; the meaning of his symptoms as a system of defense against conflict (the primary gain) and their use as a means of manipulating others in his environment (the secondary gain); and, finally, his motivation to get well.

Previous personality. The most reliable way to evaluate a person's character is to study his past performance. Despite ever increasing numbers of skillfully created personality tests, the best method of judging a person's capacity to handle a job or a specific task is his past record of achievement. This is also the best test of the patient's ability to overcome a psychiatric disorder. If the patient has previously performed well at school, at work, and in social relations, his prognosis *even without treatment* is better than that for the patient with a history of limited capacity for successful achievement.

The psychiatrist tries to estimate the patient's ego strength on the basis of his current and past performance—that is, his ability to test external reality, harmonize his drives with societal demands, integrate his feelings with his reason, feel and express love, relate intimately to others, work in a sustained and possibly even a creative but noncompulsive fashion, use his defenses and coping mechanisms flexibly in actively adapting to his environment, and, in general, derive reasonable pleasure from family life and daily

pursuits. Type and duration of treatment and, therefore, prognosis depend on evaluation of these factors.

Acuteness versus chronicity. Other variables involved in predicting the outcome being constant, the more acute the anxiety reaction, the better the prognosis. Another variable that may affect the outcome is early treatment, especially before the defenses have hardened and become resistant to change or before symptoms become increasingly elaborated and are used to elicit sympathy, release from responsibilities, or other secondary gains. The more chronic the illness, the more the patient despairs of securing relief; in itself, hope has a beneficial effect on the symptoms of anxiety.

Life circumstances. The stresses that precipitated or produced the anxiety reaction can be viewed in two contrasting ways. If the stresses related to the genesis of the illness are relatively slight, the patient may be able to overcome them more readily than if they are severe. On the other hand, if the stresses are slight, the patient's ego strength is weaker than that of the patient in whom a neurotic reaction develops only after prolonged, severe stress.

The life circumstances at the time of treatment may play a vital role in prognosis. The attitude of the family—sabotaging or cooperative, ridiculing or encouraging—is extremely important. Financial and occupational situations may also aid or interfere with the physician's therapeutic efforts.

Meaning of symptoms. If symptoms are used symbolically to compromise an inner conflict, they are more resistant to change than are nonspecific symptoms of dysfunction of the autonomic nervous system. The symbolic use of symptoms is exemplified by the nausea preceding each date of the girl who, although she has strong sexual urges, cannot "stomach" the idea of sex and may still have unconscious oral impregnation fantasies. An example of a nonspecific symptom, on the other hand, is the nausea, without definite unconscious ideation, that regularly follows a variety of stressful events. To the degree that symptoms are used to manipulate other persons, to gain love, attention, sympathy, money, or relief from responsibility, the prognosis is proportionately poor.

Motivation. The quality and intensity of the patient's desire to get well affect the prognosis and, ultimately, the outcome of treatment. The patient is involved emotionally with the doctor in various ways, but the term "transference," commonly used to describe this involvement, is too generic to be useful in psychotherapy. Transference is usually broken down into positive and negative transference, but these terms, again, tell one little about the real nature of the emotional involvement with the doctor. In addition to the strength of the desire to get well, opposed by the primary and secondary gains of the illness, the patient's emotional relationship with the doctor depends on his level of self-reliance.

Rado has characterized these levels as magic-craving, parent-seeking, self-reliant, and aspiring, as shown in Table II. He summed up his scheme in this statement: "The crucial difference between adult (realistic) and childlike (regressive) treatment behavior is that at the adult levels the patient realizes that *he* must learn to do things *for himself* (just as he has to when he wants to learn a language, play the piano, or acquire some other skill), whereas at the infantile levels he cherishes the idea that *the physician* will do things *for him*—if need be, in some magical way."

During treatment, in response to various changing factors, the patient may shift from one level of therapeutic motivation to another. The aim of treatment is to raise the patient's motivation to the highest level possible for him, but in any case the treatment selected

TABLE II
Levels of Motivation in Treatment Behavior^a

Level	Description	Clinical Example
Adult, realistic Aspiring	This level is available only in the adult patient who is capable and desirous of self-advancement by extensive learning and maturation.	"I am delighted to cooperate with the doctor. This is my opportunity to learn how to make full use of all my potential resources for adaptive growth."
Self-reliant	This level is available in the average adult patient who knows or is capable of learning the simple adaptive patterns of daily life.	"I am ready to cooperate with the doctor. I must learn how to help myself and do things for myself."
Childlike, regressive Parent-seeking level	When the adult patient feels like a helpless child, he seeks parental help and, therefore, parentifies the physician.	"I don't know what the doctor expects of me. I couldn't do it anyway. He should cure me by his efforts."
Magic-craving level	The completely discouraged adult patient retreats to the hope that the parentified physician will do miracles for him.	"The doctor must not only cure me, he must do everything for me—by magic."

and the techniques used within the particular strategy of therapy depend to a great extent on the motivational level of the patient. In general, the greater the self-reliance of the patient, the better the prognosis and the wider the range of treatment possible.

Treatment. It is hard to imagine a psychiatric disorder or indeed any medical disorder more subject to the influence of the physician and to the vicissitudes of the doctor-patient relationship than anxiety reaction. In the face of pervasive anxiety or acute, intense panic, the physician's calm encouragement and reassurance can have strong curative powers. A number of factors in Wolberg's "helping process"—placebo effect, magical expectations, catharsis, suggestion, and transference—are inevitably set in motion by the relation of the patient and the doctor. These can be aided or hindered by the appropriate or inappropriate actions of the therapist.

The patient consults a therapist with the expectation that the doctor will cure him or at least relieve his distress. The influence of this hopeful expectation (positive placebo effect) is often in itself therapeutic, especially in decreasing anxiety. In addition, most patients ascribe to the physician magical curative powers that enhance these expectations. In this setting he experiences his feelings and discharges affect, and this cathartic effect in many instances reduces anxiety even more. Under the influence of thiopental (Pentothal sodium) or amobarbital (sodium Amytal), hypnosis, carbon dioxide, or even lysergic acid diethylamide (LSD), the cathartic effect can be specifically enhanced in selected patients. Emotional arousal also seems to be a prerequisite for attitudinal changes.

The physician's words or attitudes have significant powers of persuasion acting through a process, dimly perceived and not altogether understood, called suggestion. Probably many results attributed to interpretation and the attainment of insight are due instead to suggestion. Much nonverbal, unconscious suggestion pervades doctor-patient encounters; suggestion is sometimes used directly and deliberately.

When the patient's past attitudes to significant people are displaced or transferred to the therapist, the relationship becomes endowed with a powerful tool for helping or obstructing therapeutic efforts. Unless transference begins to serve as a therapeutic obstacle, it is left alone by the therapist. In more formal psychotherapy, transference may be manipulated in the service of insight, catharsis, or even deconditioning.

Modifying stress. If the stresses creating the chronic or acute anxiety can be modified, the anxiety reaction can also be modified. Techniques of altering stress vary from advice to the patient—to leave town, take a vacation, separate from a spouse—to family therapy, in which members of the family are brought in for treatment separately or conjointly, to direct manipulation of the environment, often with the help of a social worker, by employing a housekeeper, plac-

ing a disturbed child in a treatment center, or regulating the schedule of work and play.

Taking sides in the internal conflict. Rarely does the therapist take sides in intensive psychotherapy, but this technique may be effective in briefer forms of psychotherapy. The therapist aligns himself with one side of the inner conflict, either the repressing or the repressed side and, through his added persuasive strength, breaks the deadlock leading to anxiety. This method must, of course, be used cautiously and only when the therapist understands clearly both the psychodynamics and the effects of the patient's changed behavior. In practice, the therapist usually aligns himself with the side of the conflict that prevents self-damaging behavior.

Medication. In anxiety states the tranquilizers, especially the minor tranquilizers, have been of great therapeutic aid since their advent in the 1950's. Before that, the barbiturates and other sedatives and hypnotics were in general use and, to a lesser extent, still are today. Among the barbiturates still used fairly commonly are amobarbital (sodium Amytal), secobarbital (Seconal), and butabarbital (Butisol sodium). The danger of barbiturate habituation is decreasing their popularity, and barbiturates have been largely superseded by tranquilizers. These have been used as a primary method of therapy, especially by nonpsychiatric physicians, or as adjunctive therapy along with psychotherapy, particularly by psychiatrists. Evidence suggests that the minor tranquilizers can help make the patient more amenable to psychotherapy, provided the drugs are not used to aid avoidance and denial of emotionally charged topics.

A wide variety of tranquilizers is available. Among the more popular ones in the treatment of anxiety reactions are the minor tranquilizers—meprobamate (Miltown, Equanil) and chlorthalidazine (Librium). The phenothiazines—including chlorpromazine (Thorazine), thioridazine (Mellaril), promazine (Sparine), prochlorperazine (Compazine), and trifluoperazine (Stelazine)—are usually used in treating the anxieties associated with schizophrenia or, in selected instances, agitated depression. In anxieties accompanied by mild depression, a combination of benactyzine, an antidepressant, and meprobamate (Deprol) or of amitriptyline hydrochloride (Elavil) and meprobamate is often effective.

In using medication for anxiety reactions, physicians should remember that positive placebo reactions come within 5 or 10 per cent of favorable results with minor tranquilizers. In treatment of psychoses, however, the difference between results with the major tranquilizers and those with positive placebo effects is significantly greater.

Education. In all types of psychotherapy, some education or instruction takes place, but it may be used deliberately and selectively in regulating the habits or attitudes of certain patients. If the patient is pushing himself to the brink of exhaustion by

working long hours, regulating the working day and increasing the amount of rest and relaxation may be extremely helpful. Direct counsel must be used judiciously, for the patient's neurosis may prevent him from taking advantage of changes that would obviously benefit him. In addition to changes in type or amount of work, modifications in living arrangements or religious and social life, for example, may be beneficial.

Deconditioning. Many anxieties are the result of conditioning—the association of the conditioned stimulus that becomes a stress with an unconditioned stimulus, usually on the basis of the sensory context surrounding the unconditioned stimulus. The unconditioned stimulus may be largely responsible for the pervasive anxiety that forms the background for sharper increments of anxiety, experienced as acute attacks. Time, shape, color, or functional associations may link the unconditioned and conditioned stimuli. In one patient, for example, the unconditioned stimulus was the hearse carrying her brother to his grave; thereafter, the conditioned stimuli were black cars, especially limousines, funerals, or anything reminding her of funerals, such as certain types of floral arrangements.

In deconditioning, an attempt is made to loosen the associative links between the conditioned stimuli and the unconditioned ones by systematically decreasing anxiety, starting with the least stressful and working up to the most stressful stimuli. Deconditioning techniques based on learning theory also make use of muscle relaxation, either through drugs or hypnosis or in the waking state, with decrease of the proprioceptive feedback from the muscles that keep the nervous system tuned and excessively alerted to incoming stimuli.

Insight and understanding. Most forms of psychotherapy, from brief to psychoanalytic, try to give the patient insight into his basic strivings, conflicts, defenses, and the meaning of his symptoms. The hope is that this new orientation and perspective may lead to changes in behavior that will better adapt the patient to his life situation. In brief therapy (perhaps 15 to 20 sessions), greater reliance is placed on emotional support during crises; the emphasis is on current problems, the patient's resources and coping mechanisms being allowed to regain strength and to bring him into better adaptive balance with his environment. In brief therapy, sectors of the patient's life are selected for modification, depending on which need changing the most and which can be modified during therapy. In more intensive therapy, reliance is greater on free association to promote the reconstruction of personality.

Anxiety reactions can usually be managed with brief psychotherapy; indeed, it is usually the treatment of choice. When the anxiety reaction is chronic and when deep-seated problems in identity, work, or love are also involved, psychoanalysis is recom-

mended, provided the patient has good ego strength and introspective ability and is psychologically minded. Probably not more than 10 per cent of patients with anxiety reactions are suitable candidates for this form of treatment.

Practice. Regardless of the form of treatment, the patient must practice new forms of behavior. Unless his changes in attitude are translated into behavior and are constantly practiced until they become automatic, as in learning any new skill, such as golf, tennis, dancing, or typing, treatment will have little value. A great deal of evidence supports the view that, if a person changes his behavior (perhaps by external pressures) before he changes his attitude, his attitudes will also change, until they are in line with his new behavior. In either case, the goal is to modify behavior and to maintain the new behavioral patterns by practice until they become automatic. In this fashion the patient can modify his environment or change his responses so that old stressful stimuli no longer evoke anxiety and discomfort.

Suggested Cross References

More detailed information regarding the concept of anxiety as viewed according to various theoretical positions may be found in Area C, on current theories of personality and psychopathology. Further discussions regarding the physiology of anxiety are presented in Sections 2.5 to 2.9 on neuroanatomy and neurophysiology, in which the central brain mechanisms involved in affect are reviewed, and in Malmö's section on the physiological concomitants of emotion (Section 29.4). Social and cultural determinants of anxiety are also discussed by Wallace in his section on anthropology (Section 4.1) and by Silverman in his section on sociology (Section 4.2). The various psychiatric disorders mentioned in connection with the differential diagnosis of anxiety reactions are presented more fully in the chapter on schizophrenia (Chapter 15), in Ford's section on involutional depressive reaction (Section 17.3), and in the chapters on the organic brain disorders (Chapters 18 to 21). For a discussion of the medical diseases that may present with anxiety and are involved in the differential diagnosis of anxiety reaction, see Victor Lief's section on the medical examination (Section 12.4). For more detailed descriptions of the various psychiatric treatment modalities mentioned in this section, such as psychotherapy and drug therapy, see Area G, on psychiatric treatment.

23.2 CONVERSION REACTION

JOHN C. NEMIAH, M.D.

History and Definition

"I seldom failed," wrote Axel Munthe in *The Story of San Michele*, "to attend Professor Charcot's famous *Leçons du Mardi* in the Salpêtrière, just then chiefly devoted to his *grande hystérie* and to hypnotism. The huge amphitheatre was filled to the last place with a multicolored audience drawn from tout Paris, authors, journalists, leading actors and actresses, fashionable demimondaines, all full of morbid curiosity to witness the startling phenomena of hypnotism almost forgotten since the days of Mesmer and Braid...."

"To me who for years had been devoting my spare time to study hypnotism these stage performances of the Salpêtrière before the public of tout Paris were nothing but an absurd farce, a hopeless muddle of truth and cheating. Some of these subjects were no doubt real somnambulists faithfully carrying out in a waking state the various suggestions made to them

during sleep—post-hypnotic suggestions. Many of them were mere frauds, knowing quite well what they were expected to do, delighted to perform their various tricks in public, cheating both doctors and audience with the amazing cunning of the *hystériques*. They were always ready to ‘*piquer une attaque*’ of Charcot’s classical *grande hystérie*, *arc-en-ciel* and all, or to exhibit his famous three stages of hypnotism: *lethargy*, *catalepsy*, *somnambulism*, all invented by the Master and hardly ever observed outside the *Salpêtrière*. Some of them smelt with delight a bottle of ammonia when told it was rose water, others would eat a piece of charcoal when presented to them as chocolate. Another would crawl on all fours on the floor, barking furiously, when told she was a dog, flap her arms as if trying to fly when turned into a pigeon, lift her skirts with a shriek of terror when a glove was thrown at her feet with a suggestion of being a snake. Another would walk with a top hat in her arms rocking it to and fro and kissing it tenderly when she was told it was her baby. Hypnotized right and left, dozens of times a day, by doctors and students, many of these unfortunate girls spent their days in a state of semi-trance; their brains bewildered by all sorts of absurd suggestions, half conscious and certainly not responsible for their doings, sooner or later doomed to end their days in the *salles des agités* if not in a lunatic asylum.”

It is fitting that Charcot should introduce the subject of conversion reaction—or hysteria, as he and his contemporaries called it—for it was he and his colleagues at the *Salpêtrière* in Paris, during the latter half of the 19th century, who first focused medical attention on hysteria in a thorough and systematic fashion. Charcot was not, of course, the first to recognize or describe hysterical symptoms. These had been known for centuries, although the explanation of them had varied through the ages in a series of shifting theoretical concepts that mirrors the intellectual history of mankind.

Early history. The ancient Greeks, and the Romans who borrowed from them, were aware of hysterical phenomena, which they considered a disorder of women and attributable to abnormal movements of the uterus. The term *hysteria* itself is a legacy of this physical theory, derived from the Greek *ὑστέρα* (*hys-tera*), uterus.

In the Middle Ages, when scientific interest shifted away from the physical universe to matters spiritual, the theoretical concepts explaining mental disorders changed accordingly. Hysterical and other neurotic symptoms were thought to be the result of possession by evil, external, immaterial forces—the demons and devils and their willing human victims, the witches, that fill the pages of the *Malleus Maleficarum*. Written by two Dominican monks, Heinrich Kramer and James Sprenger, as a guide for inquisitors in the diagnosis and treatment of witches, this is one of the great textbooks of psychopathology of its time, and in its numerous case histories one can read accurate descriptions of clinical syndromes that are familiar today.

When the swing of the pendulum brought a return of interest in physical phenomena, clinical medicine followed suit, and attention was focused on the nature of symptoms and, beginning in the 18th century, on their relation to physical pathology. It soon became

apparent, however, that patients often presented symptoms that appeared to represent known physical illnesses but for which no pathological lesions could be found. It was Sydenham in the late 17th century who emphasized that these hysterical phenomena could mimic almost all known physical diseases, but he offered no explanation of the mechanism of hysterical symptom formation. Hysteria was a familiar disorder to the clinicians of the ensuing 2 centuries, particularly as a stumbling block to accurate diagnosis, but it was not until Charcot began his studies that any real attempt was made to understand the syndrome.

Charcot. If Charcot’s theories and even some of his observations have proved to be misleading in the light of subsequent knowledge and if his management of patients, as Munthe suggests, was not always entirely therapeutic, the beginning of the whole contemporary movement of psychodynamic psychiatry nevertheless rests with him. The interest he showed in the entire range of hysterical manifestations and their relation to hypnosis focused attention on these phenomena and attracted many able young men to the *Salpêtrière*. Among these were Pierre Janet and Sigmund Freud, each of whom devoted himself to the study of hysteria and contributed to the theoretical formulations concerning it.

Janet. For Janet, *dissociation* of consciousness was the key concept. In the normal individual, according to Janet, his ideas and mental functions are organized into an integrated whole that constitutes the personality, and each of these ideas and functions is ordinarily available to recall at will by the personal consciousness. What characterizes hysteria is what Janet called a “retraction of the field of personal consciousness and a tendency to the dissociation and emancipation of the systems of ideas and functions that constitute personality.” The dissociated systems of ideas and functions, although no longer available to the personal consciousness, nonetheless continue to be active and, operating autonomously, create the symptoms of hysteria that appear to the personal consciousness to arise mysteriously beyond its voluntary control.

Freud. In his early work with hysteria, Freud, too, accepted the notion of dissociation, but his interest was initially focused more on the genesis of the hysterical symptoms themselves than on the nature of the mental state that underlay their production. His studies in France had introduced him to Charcot and his school, which considered hysteria to be primarily a neurological disorder. His travels also took him to Nancy, where Liebeault and Bernheim were demonstrating the almost magical effect of hypnosis in removing hysterical symptoms. The observations of the Nancy school gave strong evidence for the psychological nature of hysteria, and Bernheim and his colleagues set themselves in theoretical opposition to Charcot and his followers.

Freud's early enthusiasm for the therapeutic use of hypnosis, which stemmed from his experience in Nancy, was reinforced by the accidental observations of Breuer in Vienna. Breuer discovered in the course of hypnotizing a hysterical young woman that, when the patient was allowed to talk spontaneously under hypnosis, she described hitherto unconscious memories of emotionally traumatic events that were directly related to the production of the hysterical symptom. Moreover, the recovery of these previously unconscious memories and the *simultaneous expression of the affect associated with them* resulted in the disappearance of the symptoms. Freud confirmed in his own clinical practice the effectiveness of this cathartic method of treatment and proposed a theory to explain the formation of the symptom: the affect associated with the traumatic episode was not discharged in an external emotional expression at the time of the trauma; instead, it was *converted* into a somatic hysterical symptom that symbolically represented the traumatic incident or some aspect of it. The memory of the trauma, deprived by conversion of the affective charge, was no longer of importance to the patient and dropped out of consciousness. For Freud, the mechanism of conversion was the central feature of hysteria and became the starting point of all his later theoretical formulations concerning neurotic symptom formation.

Although Janet and investigators in the United States like Morton Prince and Boris Sidis continued to explore the process of dissociation during the early years of this century, Freud's increasingly elaborate theoretical formulations gradually gained the ascendancy in the minds of psychiatrists interested in the psychological approach to emotional disorders. Attention slowly shifted away from clinical diagnostic categories to the psychodynamic mechanisms that underlay symptoms and that provided, at least partially, an etiological explanation of their formation.

Classification and definition. In addition to their traditional concern with the psychoses, psychiatrists became increasingly interested in the psychoneuroses, psychosomatic phenomena, disturbances in behavior, and disorders of character. These factors influenced the terms used to designate various psychiatric syndromes, and thus, in earlier editions of the *Standard Classified Nomenclature of Diseases*, "hysteria" became "conversion hysteria." A further evolution of the term occurred in the American Psychiatric Association's *Standard Nomenclature of Diseases and Operations*, a major revision of the classification of psychiatric disorders that arose as a result of experience with psychiatric casualties in World War II; "conversion hysteria" became "conversion reaction," which is now distinguished from "dissociative reaction." In the latter diagnosis, Janet's term has been revived to refer to phenomena such as amnesias and fugue states, which were previously considered to be mental manifestations of conversion hysteria, and the

term "conversion reaction" is restricted to a more limited set of symptoms manifested as localized disorders of bodily function.

In the *Standard Nomenclature*, conversion reaction is defined as a syndrome in which "instead of being experienced consciously... the impulse causing the anxiety is 'converted' into functional symptoms in organs or parts of the body, usually those that are mainly under voluntary control. The symptoms serve to lessen conscious (felt) anxiety and ordinarily are symbolic of the underlying mental conflict.... They are to be differentiated from psychophysiologic autonomic and visceral disorders."

The following discussion is restricted to those phenomena contained in the official definition of conversion reaction. However, the adjective "hysterical" is occasionally employed when it is appropriate, since there is no good adjectival form of "conversion reaction," and repeatedly resorting to circumlocutions would become clumsy and boring.

Epidemiology

It is difficult to speak with precision about the epidemiology of the conversion reaction, since the statistical data that underlie epidemiological considerations are neither complete nor accurate. It is important, therefore, to view generalizations about the epidemiology of the conversion reaction with reservations and with the recognition that more systematic observations may require a revision of current ideas.

It is often stated that the conversion reaction is less frequently seen in contemporary psychiatric practice than it was 60 or 70 years ago. If by conversion reaction one means the classically described major sensorimotor symptoms of paralyses, anesthetics, convulsions, etc., there are possibly some grounds for the statement. Perhaps the most convincing confirmatory evidence comes from the comparative experience with psychiatric casualties in World War I and World War II. Granted that a battlefield is different from a civilian environment and that grossly traumatic situations are a more prominent causal factor in wartime psychiatric casualties, nonetheless there appeared to be significantly fewer military patients with certain forms of conversion reactions (e.g., tremors, gait disturbances, and convulsions) in World War II than in World War I. On the other hand, the psychophysiological reactions appeared to have increased in number in World War II. Even these generalizations are called into question by the possibility that changing diagnostic practices and theoretical constructs have influenced the statistics on which they are based. For example, the concept of psychophysiological processes (i.e., psychosomatic medicine) did not really gain currency until the period between the two wars and may have led military physicians to detect more of these in the second war.

However, even if the major motor and sensory disturbances have diminished in number, this does not

necessarily mean that the conversion reaction as such is any less frequent. It is possible that there has merely been a shift from the predominance of one type of conversion reaction to another, the total number remaining the same. Indeed, evidence from contemporary clinical experience suggests that pain and the simulation of bodily disease are the predominant forms of conversion now manifested by patients. But once again, these impressions cannot be said to be on solid ground; the total incidence of hysterical pain in the population at large, for example, is certainly not known, since the condition is probably frequently not recognized as such by the physician whom the patient consults. The increasing number of such patients seen by psychiatrists in a general hospital population may represent merely an increased awareness of the condition as a consequence of the heightened sophistication in the staff of a hospital that maintains a psychiatric service. Furthermore, it is difficult to make comparisons between the contemporary scene and that of 80 years ago. The incidence of hysterical pain for the earlier period is not known, and the seeming prevalence of the major sensorimotor symptoms may simply reflect the interest of clinicians of that day in a dramatic disorder, which they reported in their scientific writing to the exclusion of other, less interesting forms of the condition.

Another aspect of the epidemiology of the conversion is the tendency of the symptoms to spread from one individual to another. This phenomenon is rarely mentioned by contemporary observers. One may occasionally see on a psychiatric ward one patient developing the same conversion symptom initially manifested by another. Or, during an epidemic of poliomyelitis, one may find an associated small epidemic of conversion symptoms resembling those of poliomyelitis, with all the diagnostic problems that necessarily result. But for descriptions of the spread of symptoms on a grand scale, one must turn to history. Religious houses particularly appear to have been subject to these disturbances. Paul Richer in *Etudes Cliniques sur la Grande Hystérie* has described a number of such epidemics occurring in the 17th, 18th, and 19th centuries, and Aldous Huxley's *The Devils of Loudun* vividly portrays a famous disturbance in an Ursuline convent.

Pathology

There is little to be said about the pathology of the conversion reaction. There are no known neuropathological lesions underlying the symptoms, and the pathology that is associated with the condition is purely secondary to the hysterical paralyses and contractures. If these are of long duration, muscle atrophy, stiffening, and limitation of motion of the joints of the affected limb or limbs may occur as a result of the prolonged disuse.

Etiology

Early theories

Charcot. Although there had been a number of suggestions about the etiology of the conversion reaction during the earlier decades of the 19th century, it was Charcot and his colleagues who first attempted a systematic and extensive study of the nature and cause of hysteria. Charcot was a neurologist and was under the sway of the growing body of knowledge about pathological anatomy. It is not surprising, therefore, that he attributed the symptoms of the disorder to a hereditary degenerative process of the nervous system, despite the fact that such a process was not to be detected either grossly or microscopically. Although Charcot championed a physical etiology of hysteria, he was not unaware of the influence of psychological factors on the symptoms, which his experiments with hypnosis showed to be important. Charcot knew and repeatedly demonstrated that under hypnosis the symptoms of hysteria could be produced or removed at the will of the hypnotist. Furthermore, he recognized the psychological implications of the observation that patients can respond to and act on ideas introduced into their train of thoughts. But Charcot maintained that this responsiveness to ideas and the very capacity for being hypnotized occurred only in patients with hereditary hysterical degenerative disease of the nervous system. For Charcot, hypnotizability was a sign of illness, and he insisted that normal people could not be hypnotized.

Bernheim. Bernheim, who was more interested in the cure of patients with hysteria than in the scientific study of the disorder itself, made extensive use of hypnotism as a technique of treatment. In the course of his work, he made careful investigations into the nature of hypnosis itself and gained wide experience with the variety of phenomena that occur in the hypnotic state. He thought of hypnosis primarily in psychological terms and proposed that the phenomenon basic to it was suggestibility. Furthermore, his observations indicated that suggestibility and hypnotizability were normal personality functions that appeared in many people without any taint of nervous or mental disease. This contradiction of Charcot's assertion that hypnotizability was strictly pathological sired a bitter feud between the schools of Nancy and the Salpêtrière, and it was only after years of acrimonious debate that Bernheim's concepts were generally accepted.

Janet. Pierre Janet, although a pupil of Charcot's at the Salpêtrière, was an independent thinker and made many contributions to the body of theory and observations concerning hysteria. Like Charcot, he believed that hypnotizability was pathognomonic of hysteria and the ultimate and basic cause of the disorder was a hereditary degeneration of the brain. Despite

this underlying orientation, he was very much concerned with understanding the psychology of hysteria and elucidating the psychic mechanisms involved in symptom formation.

Bernheim, both from his clinical observations and from his experiments with hypnosis, in particular posthypnotic suggestion, had developed the notion of automatisms—automatic acts, the origin of which is unconscious and which take place without the conscious will of the actor being involved. Janet paid particular attention to phenomena of this sort, especially as they were observed in major hysterical alterations of consciousness, such as amnesias, somnambulisms, and multiple personalities. He proposed the concept of dissociation, in which specific networks of ideas are lost to conscious attention and volition but, although unconscious, continue to produce the sensory and motor affects that appear as the symptoms of hysteria.

Thus far Janet's theory of symptom formation was entirely a psychological one. It was only when he proposed an explanation of the process of dissociation itself that he reverted to physical concepts. The dissociation occurred, he stated, when there is a lowering of the mental energy binding together all the mental contents into an integrated personality structure, and certain groups of associations fall away by inertia and are lost to the central personality organization. This lowering of mental energy, said Janet, was the result of hereditary degeneration of the nervous system.

Freud. Freud, like Charcot, began his professional life as a neurologist. He made his first systematic attempt to explain neurotic symptoms an exercise in neurophysiology. He soon abandoned the effort, and the monograph in which he set forth his ideas, *A Project for a Scientific Psychology*, was not published until more than a decade after his death. His first public paper on psychiatric illness was "On Hysteria," written with Josef Breuer. This paper later became the first chapter in the monograph, *Studies on Hysteria*, which gave the details of their early clinical observations as well as their first theoretical formulations. The language and concepts are all psychological, and from that time on, consciously at least, Freud gave up any attempt to correlate psychological functions with neurophysiological processes.

In Freud's earliest psychiatric papers (1894 and 1895), one finds an explanation of the etiology of hysterical symptoms that became the cornerstone of the whole theoretical structure that subsequently arose. His formulation of the mechanism of conversion has been mentioned earlier—that affects associated with a psychic trauma were not expressed emotionally at the time of the trauma but were, instead, converted into physical symptoms. This provided an explanation of the mechanism immediately underlying conversion symptom formation. But there was a further observation to be accounted for—the affects

and ideas associated with them were split off from consciousness. In other words, the affects were dissociated from the main stream of consciousness and were not accessible for discharge over the normal channels of emotional expression, thus making them subject to the subsequent mechanism of conversion.

Freud and Breuer were not satisfied with the theory set forth by Janet that hereditary degenerative processes underlay dissociation. Instead, they proposed two possible alternate mechanisms by which dissociation could occur. (1) Breuer suggested that at the time of a psychically traumatic event the patient was in a temporary hypnoid state of altered consciousness. When full consciousness returned, the memories of the traumatic event and the associated affects experienced during the hypnoid state remained separated from the main body of associations constituting the normal personality. (2) Freud postulated a different mechanism: because the ideas and associated affects were morally and ethically unacceptable to the individual, they were split off from the main stream of consciousness for the purpose of sparing the individual the pain of recognizing his less honorable tendencies. In each of these instances, ideas and their related affects were dissociated, the affects were blocked from normal channels of emotional discharge, and the emotional energy thus dammed up was transmuted into physical processes by the mechanism of conversion, leading to the formation of symptoms.

Freud referred to "hypnoid hysteria" when the first mechanism of dissociation was at work, and "defense hysteria" in the case of the second. As his clinical observations multiplied, however, he discovered that hypnoid hysteria rarely, if ever, occurred in the cases he saw, and he came to recognize that defensive psychological maneuvers could result in neurotic conditions other than hysteria. What led specifically to hysterical symptoms was a disposition to conversion. If this was absent, other psychological mechanisms were employed to produce phobias, obsessions, and compulsions. Furthermore, he became aware that the unacceptable, painful affect that initiated the defensive dissociation in hysterical symptoms was invariably sexual. A further study of his cases showed him that the sexual trauma always occurred in the patient's childhood; every hysterical woman he investigated gave a history of having been sexually molested by an adult, usually her father.

By combining the various observations that had come to him piecemeal, Freud proposed in 1896 an integrated and specific theory of the etiology of hysteria: a passive sexual seduction in childhood is the specific determinant of hysteria underlying the disposition to conversion. The individual is sensitized by this childhood experience to the sexual feelings and situations arising after puberty, for these arouse the frightening affects and memory traces of the earlier sexual trauma, repression occurs as a defense, and

the sexual affect is converted into the somatic symptom.

However, further observations conflicted with this formulation and caused Freud to make a radical alteration in his theories. It slowly became apparent to him, both from his own self-analysis and from more extensive investigations of his patients' lives, that the alleged sexual seductions in childhood were not facts but merely the patients' fantasies, presented as if they had been actual experiences. It was only gradually that the significance of these observations became apparent to Freud and led him to the discovery that sexuality does not first occur in the human being only after the changes in puberty but is present as a strong and important biological drive in early childhood. The early objects of this sexual drive, moreover, are the parents of the child, leading to the now well studied and well documented Oedipus complex.

Current theory. The theory of the etiology of hysteria was reformulated in the light of these new discoveries: a fixation in early psychosexual development at the level of the Oedipus complex, with a failure to relinquish the incestuous tie to the loved parent, leads to a conflict in adult life over the sexual drive (or libido) because it retains its forbidden incestuous quality. The drive is, therefore, subjected to the defensive psychological maneuver of repression. The energy deriving from the drive is converted into the hysterical symptom, which not only protects the patient from a conscious awareness of the drive but at the same time often provides a symbolic expression of it. In this new formulation, hysteria is conceived of as a specific clinical entity arising from specific sexual conflicts originating in the oedipal period of psychosexual development.

Further clinical observations soon led to a further elaboration of the theory. It was often very difficult for patients with conversion reactions to relinquish their symptoms. This was partly because to do so would subject the patient to experiencing the mental discomfort associated with being aware of the forbidden impulse, which had been a central motivation for the formation of the symptom in the first place. But there were other secondary but important motivations for retaining the symptom once it had resulted from the basic process of conversion. The symptom itself could bring certain advantages to the patient. It defined her as a sick and disabled person, and the people in her environment acted accordingly. Attention, sympathy, and help were focused on her because she was ill, and she was not required, while an invalid, to carry out the duties and responsibilities expected of a healthy adult. Such advantages gratified the dependency needs of the patient and, because of the secondary gains resulting from the gratification, tended to reinforce the perpetuation of conversion symptoms, which had been produced in the first place

by quite different psychological factors—the conflict over oedipal sexuality.

These formulations soon became the standard psychodynamic explanation of the conversion reaction. Even now, the term "conversion" implies to many psychiatrists a psychogenic physical symptom arising from conflicts over sexuality that have their origin in the oedipal phase of psychosexual development. There is no doubt that the conversion reaction may arise on this basis alone or that such conflicts may play a part, along with other psychological factors, in producing conversion symptoms. There is, however, a growing trend in contemporary thinking to expand the concept of conversion and include a wider range of psychological events.

Expanded concepts of conversion reaction

Mixed syndromes. Conversion symptoms do not always occur in a circumscribed clinical syndrome. On the contrary, in the mixed psychoneuroses, the conversion symptom is only one of a repertoire of clinical manifestations that may include phobias, obsessions, compulsions, psychoneurotic depression, etc., in which, according to psychoanalytic theory, the psychogenetic factors are primarily preoedipal and pregenital. A particularly striking instance of this mixture is seen in the transient conversion symptoms sometimes manifested by patients with schizophrenia.

Variety of personality types. The conversion reaction is not invariably associated with the genital hysterical character. On the contrary, it is found in combination with a variety of personality types (e.g., the passive-aggressive, the schizoid, and the paranoid personality) in which, according to Freudian theory, pregenital conflicts play a predominant role.

Were these the only observations requiring an explanation, it might be argued that in these mixed clinical syndromes, the psychogenic factors were also mixed—that is, that the conversion symptoms were produced by elements arising from oedipal genital conflicts and that the other symptoms arose from earlier preoedipal, pregenital conflicts existing simultaneously in the patient. This explanation preserves the theoretical notion that conversion symptoms are specifically associated with oedipal genital sexual drives. It is, unfortunately, not supported by more recent observations, as Rangell has pointed out, which indicated that preoedipal sexual drives and the aggressive drive may be processed by the mechanism of conversion and expressed symbolically in physical symptoms.

A man of 30 developed a low back pain following a back injury and underwent a laminectomy for the removal of an L-4-5 disk. After surgery he continued to have moderate pain, diagnosed as arachnoiditis. Despite this, he managed to keep on with a full life of work and activities. Finally, at his family's urging, he agreed to further surgery. After the operation, he became totally bedridden and incapacitated—not because of pain but because of an extensive weakness of his entire spinal and neck musculature that prevented him from walking or even

sitting. The weakness was clearly hysterical in nature. Investigation under sodium Amytal narcosis uncovered the fact that the patient had been utterly opposed to further surgery and had deeply resented his family's pressure, to which he had finally felt he must submit. As he described all this under narcosis, he began to express bitter anger at his family. Speaking of at last agreeing to the operation, he said, "So I finally decided if I had to cut my throat, I *would* cut my throat—and here I am; the family needed a lesson." When fully conscious both before and after the Amytal interview, the patient consciously felt and exhibited no anger whatsoever toward those who had forced him into surgery. This had been translated by conversion into the physical symptom of muscular weakness, which, without his being aware of its meaning or the feelings it expressed, gave him the means for revenge against his family.

Gratification of dependency needs. It has long been known that hysterical symptoms may result from a frightening physical accident that produced no bodily injuries. "Railway spine," the name attached to the hysterical sensorimotor phenomena seen in people who had been involved in a railway mishap, was a well described entity in the 19th century. During World War I, much interest and attention was focused on the traumatic neuroses, in which conversion symptoms were frequently manifested. It became apparent that the primary motivation for these symptoms was self-preservation rather than oedipal genital drives; that is, the symptoms enabled the patient to escape a dangerous situation, to be relieved of onerous responsibilities, and to receive protection, help, and attention.

The increasing preoccupation of psychiatrists over the past 2 or 3 decades with the psychological aspects of bodily disease has revealed that these oral narcissistic drives are central etiological factors in many patients with conversion symptoms, especially when the conversion process results in pain or in the prolongation or exacerbation of bodily symptoms originally resulting from a local physical lesion. In such patients, the symptoms are motivated by and provide gratification for strong, unconscious dependency needs. These needs are a source of conflict for the patient, since they run counter to the image of himself as a strong, self-sufficient person, which he must preserve in order to maintain his self-esteem. Since his symptoms appear to the patient to be the result of a bodily illness that has afflicted him without his consent or participation, he can allow himself to become an incapacitated invalid, dependent on others for help and attention. Continuing to believe that he wants to be strong, self-sufficient, and independent, he remains unaware of his underlying dependency needs and can blame his entire predicament on an accidental, ego-alien sickness that is not his fault.

The fact that compensation for industrial and other injuries is often an important factor in producing or prolonging these conversion symptoms is not a justification for establishing a separate category of compensation neurosis. The monetary award is only one of a number of circumstances that provide gratification for the patient's dependency needs. His needs are

also gratified by the sympathy, concern, and tangible help of relatives, friends, physicians, and others concerned with taking care of him. Furthermore, response from people in his environment is not the only, or even the principal, cause of his symptoms and of his demands for dependency gratification through the language of bodily disturbances. The inner psychodynamic conflict over his dependency needs is an equally important part of the problem. It is only through a combination of all these causal factors that the conversion reaction finally results.

Reaction to environmental stresses. The inhuman and all too frequently unbearable pressures that World War I heaped on the men that fought it not only led to changes in the conception of human drives but forced students of human behavior to consider the environmental stresses with which human beings have to cope. By various and devious routes, theorists like Kardiner and Hartmann have approached an adaptational concept of human behavior and psychological function. At the same time, learning theorists such as Dollard and Miller and psychiatrists such as Cameron, influenced by the principles of learning theory, have attempted to adapt the generalizations derived from experimental psychology to an explanation of human psychopathology. For the latter theorists, psychiatric symptoms are not only pathological adaptations to external stimuli but learned responses. The learning is reinforced and facilitated by the reduction of the intensity of an inner painful psychological drive that follows the response.

In the case of a hysterical paralysis, for example, the initial episode of paralysis results in a reduction of the painful drive of fear or anxiety. The psychological relief thus obtained *reinforces* the hysterical response that has produced it and predisposes to a repetition of the same palliative response each time the anxiety occurs. In this way a pattern of behavior is evolved that may become chronic.

These theoretical conceptions have added an important dimension to understanding the mechanism of the production of hysterical and other symptoms by focusing attention on the importance of the environment and on the complexities of the organism's adaptational responses to it. They have also provided a basis for the contemporary experiments in behavior therapy. At the same time, there is a danger that a too exclusive interest in the phenomena of learning and adaptation may overshadow the recognition of the importance of unconscious psychic forces and lead to a neglect of the basic biological drives and the hereditary factors involved in the development of both drives and ego functions.

Psychophysiological reactions. Another factor that has had an influence in bringing about changes in the concept of the conversion reaction has been the interest, over the past 3 decades, in the psychophysiological reactions, more commonly referred to as psychosomatic disorders. As has been noted earlier,

the American Psychiatric Association *Standard Nomenclature* states that conversion reactions "are to be differentiated from psychophysiologic autonomic and visceral disorders." This differentiation is generally made on the basis of two criteria: (1) Conversion symptoms affect and are mediated by the voluntary sensorimotor system, whereas psychophysiological reactions are the result of autonomic nervous system discharge. (2) The conversion symptom expresses *symbolically* an idea or memory that is unconscious. In the psychophysiological reaction, no such symbolism is found. The autonomic response is merely the physiological correlate of an unconscious affect or drive, which leads to dysfunction in various organ systems and may, if the dysfunction continues long enough, result in actual lesions in the organ involved.

A number of contemporary investigators, such as Ziegler, have challenged the validity of making such a sharp distinction. Their arguments are based on at least three observations. (1) Certain symptoms (such as nausea, vomiting, and fainting) that have always been considered part of the classical syndrome of conversion hysteria are mediated in part, at least, over the autonomic nervous system. (2) Psychophysiological reactions may, like conversion reactions, be nonverbal, symbolic communications expressed in body language. (3) In psychophysiological reactions as well as in conversion symptoms, an affect or drive that is rendered unconscious by repression appears to be converted into a somatic symptom. It is also relevant to note here the observation that, under hypnosis, suggestions can influence functions mediated by the autonomic nervous system, indicating that, anatomically and physiologically, the cleavage between the autonomic and voluntary nervous systems is not an absolutely sharp one.

Among current investigators, positions range all the way from the distinct differentiation proposed in the American Psychiatric Association nomenclature to those who hold that all somatic processes correlated with repressed affects are brought about by the mechanism of conversion. In between these opinions are the inevitable shades of gray. A part of the disagreement rests on differences in the definition of syndromes, the causes of which are as yet poorly understood. Obviously these issues cannot be settled without further investigation and knowledge. It is perhaps not so important what terms a person chooses to use as that he defines them accurately.

Symptom as communication. Another and more recent approach to the conversion reaction is based on the study of communication in the interpersonal situation. In this framework, the conversion symptom is looked on as a nonverbal communication in body language that has, as its basic purpose, the intent to coerce another person to some action, such as helping or paying attention to the individual who is communicating. Szasz, who has explored this concept to

its furthest reaches, doubts that the conversion reaction is really an illness at all. He proposed that it is more in the nature of a game played by the participants in conformity with certain rules of communication that determine the form of the reaction. He suggested, furthermore, that the traditional medical model may not be the most appropriate conceptual framework in which to study the conversion reaction (and other syndromes); it may, indeed, blind investigators to the true nature of the phenomena they are observing.

Interesting and provocative as some of these more recent propositions have been, they appear to be based primarily on the symbolic and communicative aspects of the conversion reaction and on its function as a means of expressing dependency needs, either as secondary gain or as arising from a primarily oral organization of the personality structure. As such, they are concepts derived from a limited view of conversion symptoms and cannot be considered as theories that will ultimately or basically explain all the clinical observations.

Reappraisal of conversion reaction. In recent years, there has been a recrudescence of interest in the mechanism of conversion reaction and a beginning reappraisal of its nature. The concept of conversion was one of Freud's earliest psychological theoretical formulations, and it arose at a time when he was trying to explain why some neurotic patients developed hysterical sensorimotor symptoms and others fell prey to obsessions or phobias. He recognized that behind all these clinical manifestations there was a splitting off from consciousness—a dissociation—of painful affects and their associated ideas. The theoretical problem was to explain the subsequent choice of symptoms once the basic process of dissociation had occurred. It was to solve this problem that Freud postulated two further secondary mechanisms: (1) In hysteria the affect is *converted* into physical symptoms and discharged over this pathway. (2) In phobias and obsessions, the affect remains in the psychological realm but becomes detached from the unbearable idea that originally provoked it and is *displaced* to a neutral, unimportant, and innocuous idea, which then provides an avenue for the expression and discharge of the affect.

In this formulation, the concept of conversion carries the idea that it is a special pathological process in which psychic energy is transmuted into a physical neuronal discharge leading to the sensorimotor symptoms. Freud was himself puzzled by the nature of the mechanism and spoke of "the mysterious leap from the mental to the physical" that characterized hysteria. One might, however, ask whether conversion is such a unique process, whether it is a mechanism specific to the formation of hysterical symptoms, and whether, indeed, it is any more mysterious than or different from the translation of any idea into a volitional motor act. A normal woman in coitus

under the influence of consciously felt sexual desire will voluntarily and happily perform the bodily movements appropriate to the sexual act. A hysterical woman, without any conscious experience of sexual feelings and wishes, will have a hysterical convulsion in which she exhibits all the movements of coitus without being at all aware of their significance. What distinguishes the two women is not a difference in the way their sexual desire (a mental phenomenon) leads to the physical movements of coitus (a bodily phenomenon). The difference is that, in the hysterical woman, the process takes place in a dissociated state outside of her conscious awareness. The problem of how the mental phenomenon of volition is related to its corresponding physical bodily movement has been a puzzle to philosophers since Descartes. Conversion is simply this same process taking place in a state dissociated from conscious awareness.

If conversion proves not to be a unique mechanism specific to hysterical symptoms, attention is focused once again on dissociation as the basic psychopathological mechanism, not only for hysteria but for all psychoneurotic syndromes. The question of symptom choice becomes the problem of explaining not why a dissociated impulse or affect is expressed in a physical, bodily manifestation—which is the normal outcome of unblocked, uncontrolled affects and impulses—but rather why these mental events do not show their physical correlates but are shifted (displaced) to other mental phenomena in the form of phobias and obsessions.

All of this has a bearing on the term “conversion reaction” applied by the American Psychiatric Association *Standard Nomenclature* to some of the symptoms previously included under hysteria. Unlike the terms “phobic reaction” and “obsessive-compulsive reaction,” which refer specifically to observable clinical phenomena, conversion reaction refers to a hypothetical psychopathological mechanism. It is, furthermore, distinguished from dissociative reaction, which is treated in the *Standard Nomenclature* as a separate entity.

The wisdom and validity of the use of the label “conversion reaction” to designate a clinical syndrome of symptoms distinct from dissociative phenomena is open to question. What are called conversion symptoms are frequently found in conjunction with dissociative phenomena. It is possible that dissociation is the basic mechanism behind all the clinical phenomena now separately categorized as dissociation and conversion reactions, which are only different manifestations of the basic process. *The effect of the process of dissociation itself* is seen in such clinical symptoms as amnesias; *the effect of the dissociated mental contents* is seen in somatic processes, which range from highly complicated patterns of behavior (as in the multiple personalities) to partial, fragmented, symbolic representations of the dissociated mental contents (such as the sensorimotor phenomena referred to through-

out as conversion symptoms). By advocating the term conversion reaction, the *Standard Nomenclature* focuses on a hypothetical construct that may eventually require revision. At the same time, it diverts attention from the concept of dissociation, which may have more general applicability than the area assigned to it in the nomenclature and which certainly warrants far more scientific study and clarification than it receives in current psychiatric investigation.

Clinical Description

Although it occurs in males, especially when financial compensation is a factor, the conversion reaction is predominantly a disorder of females. Not enough is known of its natural history to speak dogmatically about its course; it frequently begins in adolescence or early adulthood, but the symptoms may appear for the first time during middle age or even in the later decades of life. The manifestations may be sporadic and episodic, often arising at times of emotional distress resulting from external crises; the site and nature of the symptoms may vary within the same person from time to time, often with a surprising fluidity, or a single symptom may become rigidly fixed and persist intractably for years.

Physical characteristics. As Sydenham knew, the manifestations of the conversion reaction are protean and may mimic most of the known bodily diseases. They can be divided into four major categories: motor disturbances, sensory disturbances, conversion symptoms simulating physical illness, and conversion symptoms complicating physical illness.

Motor disturbances. There are two kinds of motor disturbances: abnormal movements and paralyses.

Abnormal movements. The abnormal movements may take many forms. Gross, rhythmical tremors of the head, arms, and legs are seen, sometimes present when the limb is at rest, sometimes when it is in use, and commonly worse when attention is called to the movement. A variety of choreiform tics and jerks may be observed; these are usually more organized and stereotyped than the movements of true neurogenic chorea.

Convulsive movements of the entire body are sometimes found; unlike true neurogenic epilepsy, hysterical seizures are characterized not by rhythmical clonic movements of the extremities but by a wild, disorganized, seemingly unpatterned thrashing and writhing of the body. The patient appears to be completely out of control, her bedclothes are thrown into complete disarray, her arms and legs bang about with abandon, but she rarely hurts herself, bites her tongue, or voids. Such seizures may last many minutes and are accompanied by what appears to be complete unresponsiveness. Careful observation, however, will reveal that, in fact, the patient does react to stimuli; she often resists movements of her limbs forced by the examiner; though her eyes are closed, the lids

often flutter, and she vigorously resists attempts to open them. When the patient recovers from her seizure and becomes responsive, she can often remember or can be made to remember what was going on around her during her convulsion. This is quite different from the complete amnesia of the patient with neurogenic epilepsy for the events occurring during the period of true physiological unconsciousness. The hysterical patient exhibits an altered state of consciousness, but it is a dissociative state rather than the unconsciousness accompanying gross disturbances of the brain function.

Astasia abasia is also seen. This is a dramatic disturbance of gait characterized by gross, irregular pseudoataxic jerky movements of the trunk, dancing, staggering, drunken steps, and a wild thrashing and waving of the hands and arms as the patient seems to try to keep her balance or clutches for the support of walls, furniture, or people. She rarely falls; but if she does, she avoids injury.

Paralysis. Paralysis and paresis most commonly affect the extremities as a monoplegia, a hemiplegia, or a paraplegia. The affected parts are flaccid in character or show the result of sustained contractures in antagonistic muscle groups. The paralysis does not conform to the pattern resulting from damage to the peripheral or central nervous system; rather, it follows a distribution conforming to the conventional idea of the part affected. The hand is paralyzed from the wrist down, the forearm from the elbow, and the whole arm from the shoulder down. If the problem is one of paresis, the weakness may be most severe at the proximal portion of the limb rather than distally—the opposite of what occurs in central nervous system disease. For example, in hysterical hemiplegia, the patient, when walking, drags the affected leg along limp behind her rather than swinging it through at the hip, as in neurogenic hemiplegia.

When the paralyzed or paretic part is examined carefully, it readily becomes apparent that there is no genuine deficit in muscle function. If the patient is asked to move the afflicted member, one may note a spasm of the antagonist muscles; this prevents motion. In passively flexing the paralyzed limb, the observer may find a contracture of the muscle groups opposing the movement. Reflexes remain within the range of normal, the plantar response is always flexor, and there is no reaction of degeneration on electrical stimulation.

A special and localized form of paralysis occurs in the muscles affecting the vocal cords, leading to hysterical aphonia. In this condition the patient is usually able to whisper with no difficulty but can make no vocalized sound whatsoever. Examination reveals normal movement of the lips, tongue, and pharynx and of the vocal cords during respiration.

Sensory disturbances. Hysterical disturbances of sensation, especially anesthetics, may go unnoticed

unless they are specifically looked for, since patients do not often complain of them.

Skin. The disturbances of skin sensation may occur in any location, shape, and pattern. Most commonly, the sensory disturbances are found in the extremities. When disorders of motor function occur—whether abnormal movements or paralyses—these are generally accompanied by diminished or totally absent sensation. All modalities are involved, and, as with the motor disorders, the distribution of the sensory disturbance follows a pattern determined by the patient's idea of the limb affected rather than by the neural structures innervating it. Thus, one finds the characteristic stocking and glove anesthesia of the feet and hands, which, as the term implies, is distributed over the area normally covered by those bits of apparel. If the whole arm or leg is involved, the line of demarcation from head to perineum is exactly in the midline; this differs from what is found in hemianesthesia resulting from neurological disease, where the extension of terminal sensory nerve fibers across the anatomical midline preserves a small margin of sensation on the affected side.

Sense organs. The special organs of sense may also exhibit a loss of function, the patient manifesting varying degrees of deafness and loss of vision. The disturbance may be unilateral or bilateral, and a peculiar feature of the visual disorder is a regular, concentric diminution of the visual field that, in its extreme form, leaves only central vision intact, the "gun barrel vision."

The exact nature of these disorders of sensation is not clear. Although the patient will allow herself to be subjected to painful stimuli (such as pin pricks, pinching, or deep pressure in the affected area) without appearing to feel or be aware of discomfort, there is often evidence in specific testing that sensation is not completely eradicated. Certain observations of this sort indicate that peripheral stimuli are being received, transmitted, registered centrally, and used in integrated actions but that at the highest levels of mental function the patient remains totally unaware of them. One can, for example, with the patient blindfolded touch normal and anesthetic areas in random order, instructing the patient to say "yes" when she feels the stimulus, "no" when she does not; many patients will regularly reply "no" each time the disturbed area is stimulated. In patients with one eye totally blind, diplopia can be produced by pressure on the affected eyeball. Patients with bilateral blindness manage nonetheless to walk about easily and surely without bumping or harming themselves. A young lady complaining of total blindness in both eyes asked for a glass of water. It was placed on her bedside stand, precariously balanced on the edge so that the slightest touch would send it crashing to the floor. When told to reach out for it, she stared vacantly ahead and with her hand felt all around the periphery of the glass. So accurate and delicate were her movements

that she exactly outlined the circumference of the glass without once touching it and then in disgust asked that it be handed to her since she could not find it.

Hallucinations. In addition to the diminution or absence of sensory function, there may be sensory hallucinations. Although uncommon, the most frequently affected modality is vision, and visual hallucinations (excluding the toxic deliria) are almost always hysterical. Characteristically, they are of complex scenes or fragments of action that appear repeatedly and with stereotyped repetition, often reproducing the scenes of a real past event of emotional significance to the patient.

Pain. A form of sensory disturbance that is of particular importance in the conversion reaction as it is seen in contemporary psychiatry is pain. Like much else connected with this neurotic syndrome, the exact nature of hysterical pain and the mechanism of its production are not clearly understood. Possibly it is based on a heightened awareness of the myriad little stimuli normally arising from all parts of the body that are ordinarily ignored but may be perceived and even felt as uncomfortable if one focuses one's attention on them. Whatever its origin, hysterical pain is common and may affect any part of the body.

A common site is the abdomen, which has led to frequent misdiagnoses and much unnecessary surgery. Typically, a first attack occurs during adolescence and leads to the removal of the appendix, which, on pathological section, proves to be normal. The subsequent recurrence of abdominal pain is interpreted as resulting from adhesions, an ovarian cyst, or cholecystitis. With each attack, another laparotomy is performed, leaving the patient in middle life devoid of her dispensable abdominal organs and with a scarred belly wall that has been called the "battle-ground" or "checkerboard abdomen."

It is not only the physician's ignorance of hysterical pain that leads to such a clinical course; the patient herself contributes to the problem. The pain of which she complains is often vague, diffuse, poorly described, and imprecisely localized, leading to difficulties in diagnosis. Furthermore, although she cannot describe its characteristics with precision, the patient nonetheless leaves no doubt about the suffering it is causing her, often elaborating on the acuteness of her anguish in such a heartfelt way that the sympathetic physician's wish to help is easily aroused. More than this, it is evident in some patients that their symptoms and behavior are a none-too-subtle demand for surgery, or, if this is not obvious, at least the patient raises no objection to operation after operation.

Because the conversion reaction manifested as pain is common, because it may be confused with pain arising from local lesions requiring surgery or other physical treatments, and because the nature of the symptom brings the patient, initially at least, to the nonpsychiatric physician, it is essential that the physi-

cian be aware of hysterical pain and of the uses to which the patient puts it in her demand for therapeutic action.

Conversion symptoms simulating physical illness. It is apparent from the preceding discussion that the symptoms of the conversion reaction may simulate bodily disease so cleverly that diagnosis is difficult to establish. In a special form of the conversion reaction that is closely related to the problems with pain already considered, an identification with the symptoms of the illness of a person with whom the patient has a close relationship is a key mechanism. This identification is commonly with a person who has recently died, and it is often accompanied by the signs and symptoms of a pathological grief reaction. Here, too, pain is a common complaint, but many different kinds of somatic symptoms may arise in this fashion. A young man, for example, consulted his physician for severe precordial chest pains, which, he was convinced, were evidence that he had a fatal heart disease. Careful and repeated physical, laboratory, and electrocardiographic examinations disclosed no indication of cardiac difficulty, but a careful history revealed that the patient's father had died suddenly of a second episode of myocardial infarction several months before. Neither at the time nor since had the patient experienced any conscious grief for his father; instead, he developed symptoms like those of his father's fatal illness and, to his own amazement, adopted a number of his father's characteristic behavior patterns.

Identifications leading to symptoms may occur for other reasons. Freud's patient Dora, for example, developed a hysterical cough through identification with the same symptom in an older woman she felt to be a rival. On occasion, one may find rhythmical, hard abdominal pains in a man whose wife is in labor. This identification with a feminine object and function has its institutional counterpart in the *couvade* of many primitive peoples.

Conversion symptoms complicating physical illness. The symptoms of physical illness may be protracted or complicated by symptoms resulting from a conversion reaction. Pain that begins as a result of a local disease process may be prolonged as a hysterical symptom long after the physical lesion has healed. Occasionally one sees patients who, after a true epileptic seizure, continue to have hysterical seizures that closely imitate the initial spells. More perplexing and more difficult to evaluate are those patients who manifest symptoms resulting from a local bodily lesion but in whom the severity of the complaints and the magnitude of the disability are far greater than what would be expected from the nature and extent of the local lesion alone.

The diagnostic problem here is not one of deciding between a conversion reaction and a physical disorder but of trying to decide how important the psychological factors are in delaying a patient's return to an active, gainful life. Patients who fall into this category

are among the most difficult that physicians have to deal with, because of both the complexity of the clinical ingredients and the refractoriness of such patients to programs of treatment and rehabilitation. Patients in this category of conversion reaction provide good illustrations of somatic compliance, a common mechanism that enters into the formation of conversion symptoms. As the term implies, conversion symptoms tend to appear in locations and organ systems that are or have previously been the site of symptom-producing lesions, the existence of the physical disorder apparently facilitating the subsequent appearance of the conversion symptoms in the same location.

Behavioral characteristics. The patient with a conversion reaction does not show major abnormalities in her mental status. She is alert, completely oriented, and in good rapport with the examiner. Her mood may be variable, but she is not profoundly depressed or retarded on the one hand or elated and hyperactive on the other. Her thought content is not grossly abnormal, nor is there evidence of a primary process thought disorder. If she manifests hallucinations, she is aware that they are hallucinations, no matter how vivid and real the sensory images may be to her. In short, the patient's mental status reveals no indications of a psychosis or of a gross physiological disturbance of brain function.

La belle indifférence. The most characteristic behavioral feature in patients with a conversion reaction is what the French authors of the 19th century called *la belle indifférence*. Despite what appear to be the most extensive and crippling disturbances in function, the patient is herself completely unconcerned and, indeed, may not spontaneously mention such disturbances, which often results in their being overlooked unless specifically searched for. The phenomenon of *la belle indifférence* is strikingly demonstrated in a patient described by Pierre Janet in *The Major Symptoms of Hysteria*:

A young girl of about twenty had met with a rather serious accident. She fell through a glass door, and a piece of glass cut into her right wrist just below the thenar eminence. The hemorrhage was stopped, and the wound had united fairly well, when, a few days after the accident, the young woman presented herself for treatment. She experienced a certain numbness in her right hand, but no paralysis was present. She complained particularly of a persistent insensibility, most inconvenient, in the palm of her hand; this slight anesthesia about the fingers was in fact complete at the level of the thenar eminence. The case was evidently one of more or less complete severing of the median nerve, and especially of its superficial branches. But while accepting the observation of the patient, we made a singular discovery. She was a hysterical, and on her entire left side she was completely anesthetic, of which fact she had not said a word. The physician joked to her about it: 'How is it, miss, that you come here complaining about an insensibility that affects but a small portion of the palm of your right hand, while you do not even notice the much larger insensibility of the whole of your left side?' The poor girl looked surprised and ashamed. To our mind she might have replied to her doctor with much more assurance, and said: 'Be that as you think, sir, I came here to tell you what ails me; it is the in-

sensibility of the palm of my right hand that troubles me, and that of my left side has never given me any trouble. You are the doctor; explain it as you like.'

Janet's patient not only provides a vivid example of *la belle indifférence* but also demonstrates an important characteristic of it as well: The lack of concern applies to the conversion symptom or symptoms alone—it is not a general indifference or absence of anxiety. On the contrary, as in Janet's example, where the patient retained the capacity to be very much concerned about the neurological sequelae of an accident, hysterical patients often experience diffuse anxiety and other painful affects concomitant with the presence of conversion symptoms about which they remain indifferent.

The hysterical personality. Although hysterical patients do not show the major abnormalities of mood, thought, and behavior listed in the formal mental status examination check list, they often tend to exhibit subtler forms of behavior patterns that comprise what is called the hysterical personality. These are generally to be observed during the taking of the history and the initial examination. Although there may be some overlapping of the areas of behavior designated by the adjectives applied to the hysterical personality, they may be described as behaving in all or many of the following ways.

Dramatic. The patient tells her history and describes her symptoms, especially when it is pain, in vivid, colorful language. She is often discursive and circumstantial in her account, recounting how her symptoms have affected her life and relationships with people rather than giving a description of their nature, character, location, onset, and duration—all of which she tends to overlook. Her description of previous encounters with doctors is interlarded with recitations of what she said to the doctor and what he said to her.

Exhibitionistic. Hysterical patients are often overly made up and overdressed for the occasion, whether it is a visit to the doctor's office or a stay in a hospital bed. They tend to be revealing of their bodies and during physical examinations will expose more of themselves than is necessary for the part being examined.

Narcissistic. They show a predominant preoccupation with themselves and their own concerns and interests to the exclusion of those of others. They require and seek open and direct admiration and praise from other people.

Emotional. In tone and intensity of voice, by gestures, and in their language, hysterical patients freely express the whole gamut of emotions in an often bewildering array and at times in such a histrionic fashion that they give the impression of playacting and of not really being capable of experiencing lasting, real, or profound emotions.

Seductive. Such patients are often coy, flirtatious, and seductive. This impression is gained partly from

the quality of exhibitionism mentioned earlier and is reinforced by the patient's facial expression, movements, gestures, verbal innuendos, and even openly seductive invitations to sexual activity. Paradoxically, such patients are in actuality often sexually frigid.

Dependent. Although it may not always be evident in one's initial observation of the patient, it frequently becomes apparent, as the doctor-patient relationship develops, that she is overly dependent, needing not only the gifts of praise and admiration, mentioned as a part of her narcissism, but more direct evidence of help, such as advice and medications, which she demands with increasing insistence. She is, moreover, capable of anger, at times reaching the proportion of violent temper tantrums, if she feels that her needs are not being properly satisfied.

Manipulative. Finally, the patient is very skilled in getting what she wants from other people by using a variety of artful maneuvers, such as threats to produce a fit of temper, attempts at suicide that are aimed at influencing others rather than being basically self-destructive, or behavior that otherwise plays on the guilt of others.

The condition of the hysterical personality is far more extensive than that of the conversion reaction and is predominantly a pattern of behavior found in women. When it is observed in men, it is usually in association with passive, feminine, homosexual character traits. Earlier observers were of the opinion that patients with conversion symptoms almost invariably showed the traits of the hysterical personality, although the reverse was not the case, but more recent observations indicate that this conjunction is by no means invariable. Conversion reactions, especially in men, may occur in patients exhibiting a wide variety of personality patterns, even in schizophrenics.

Diagnosis

From this review of the symptoms and signs of the conversion reaction, it is apparent that it is not always easy to establish the diagnosis. Generally speaking, the phenomena of abnormal movements, paralyses, and anesthetics present few diagnostic problems, since the examiner readily elicits the characteristics that are pathognomonic of the condition. It is when one is dealing with pain and other symptoms simulating bodily disease—whether these result entirely from the process of conversion or represent emotional complications of physical disease—that difficulties arise.

It is an unsound, though tempting, practice to consider any symptom the product of a conversion reaction when all physical causes have been ruled out by the absence of physical findings and normal results in laboratory and X-ray examinations. The diagnosis thus arrived at is more indicative of the physician's ignorance than of the mechanism of conversion. The

diagnosis of conversion reaction must rest on a history and observations positively indicating its existence.

That pain or other local symptoms are wholly or in part the manifestation of a conversion reaction is strongly suggested by a presence of all or many of the following additional factors: (1) a history of other symptoms (past or concurrent) that clearly have the characteristics of a conversion reaction, such as paralyses and anesthetics; (2) a history of other overtly psychoneurotic symptoms, such as anxiety, depression, obsessions, and phobias; (3) a past history of multiple illness, possibly resulting in surgery, for which no clear cut physical origin has been found; (4) a history of sexual disturbances, with frigidity and a distaste for sexuality playing a prominent role; (5) the manifestation of the behavioral characteristics of the hysterical personality; (6) the presence of *la belle indifférence*; (7) the recent death of a person important to the patient or of other disturbances in personal relationships temporally related to the onset of the symptoms.

In establishing the diagnosis, one's approach to the patient is of central importance. Confronting her with direct questions requiring direct answers will frequently elicit no information or will yield misinformation. The patient is often quite unaware of the relation of difficult environmental situations to the appearance of her symptoms. She may not even be conscious of the fact that she is emotionally upset by what is happening in her life. Only by allowing the patient to talk in her own way about her illness and by using the more non-directive forms of interviewing techniques will the physician be able to elicit associations from the patient that will give him clues to the presence of problems indicating that the mechanism of conversion is playing a part in the formation of symptoms. And it is only by permitting the patient to talk spontaneously, at length, and without controlling interventions and interruptions by the physician that he will be able to observe convincing evidence of the behavior patterns that characterize the hysterical personality.

Finally, psychological tests may add confirmatory observations to the clinical findings. Projective tests, such as the Rorschach or the Thematic Apperception Test (T.A.T.), which are essentially special forms of the clinical interview, mirror the observations made in less structured clinical settings. As compared with patients suffering from other neurotic syndromes, those with conversion reactions give test responses that are freer and more imaginative, accompanied by a more labile affect and a tendency toward impulsiveness. Using the Minnesota Multiphasic Personality Inventory, a specific profile has been derived that correlates to a statistically significant degree with clinically diagnosed conditions involving somatization, including psychosomatic disorders as well as conversion reaction, but the test results do not separate out the conversion reaction as an entity distinct from all other syndromes.

Differential diagnosis

Central nervous system disease. The earliest manifestations of central nervous system disease may be confused with the conversion reaction. A transitory disturbance of vision in one eye or a passing weakness of an arm or leg that heralds the onset of multiple sclerosis, leaving no definite neurological sequelae or signs, may lead the unwary to dismiss the complaints as conversion symptoms. The problem is compounded by the fact that conversion phenomena may be of short duration and that female patients with early multiple sclerosis may exhibit behavior characteristic of the hysterical personality. In such cases, it is important to follow the patient carefully for subsequent episodes in which the emergence of neurological signs, or the lack of these, along with emerging positive indications of a conversion process aids in making a definite diagnosis.

Schizophrenia. The fact that hysterical patients sometimes present with hallucinations leads to a diagnostic confusion with schizophrenia. In general, schizophrenic hallucinations are auditory and are often bizarre and vague in content and form. Hysterical hallucinations, on the other hand, are usually visual and represent complex, elaborate scenes that are repeated in a stereotyped fashion. The hysterical patient does not show the gross disturbances of thought and affect that characterize schizophrenia. It must be remembered, however, that the schizophrenic patient may develop conversion symptoms. In such cases, the diagnosis is determined by the thought and affective disturbances rather than by the presence of a conversion symptom.

Malingering. A distinction that is sometimes particularly difficult to make is that between conversion reaction and malingering. The tendency of many hysterical patients to be histrionic and to use their symptoms as a vehicle of communication and coercion of others plus the often obvious secondary gain to be derived from symptoms conspire to convince the observer that the patient is consciously simulating illness to obtain her own ends. Patients with true, conscious malingering appear to be rare; in general, there are more inconsistencies in their histories as they are repeated to various people, and the patient consciously simulating a disease often deliberately produces physical signs and findings, which is a rare pattern of behavior in hysterical patients. Finally, as one works with hysterical patients, one finds increasing evidence of the use of the mechanism of repression, leading to minor dissociative phenomena.

Prognosis

Like so much else connected with the conversion reaction and the other psychoneuroses, good observations leading to valid generalizations about the prognosis in both treated and untreated patients are hard to find. From general clinical experience one knows

that some patients may develop transitory conversion symptoms that clear without any treatment at all, whereas others have clinical manifestations that remain fixed and totally intractable to therapeutic measures for years. Little is known about the natural history of the conversion reaction. The rare systematic studies of prognosis, such as that by Slater, indicate that, although 50 per cent of patients will have lost their symptoms at the end of a year from the time they are first seen, 30 per cent will still have symptoms at the end of 5 years, and 20 per cent will retain them for 15 years or longer. The exact rate of recurrence is unknown, but clinical experience indicates—as the name conversion reaction implies—that symptoms tend to come and go in response to environmental stresses.

Probably the most important factors in determining the prognosis have little to do with the nature of the manifest symptoms; rather, they are concerned with the patient's personality traits and psychological conflicts. Factors that make for a good prognosis, especially when skilled psychotherapy is available, are: (1) a psychological conflict that centers primarily around genital, oedipal sexuality; (2) evidence of stability in relationships, as indicated by generally good relationships with family and friends and a stable work history, when the latter is applicable; (3) the ability to relate to the physician and to develop a therapeutic alliance; (4) the capacity to feel and to express emotions without developing incapacitating anxiety or depression; (5) the ability to have psychological distance from consciously experienced emotion; (6) the capacity for introspection; and (7) symptoms that are fairly well circumscribed and related to definite environmental stresses.

Management

As in determining prognosis, the choice of therapy rests not on the nature of the symptoms but on the personality structure. The factors pointing to a good prognosis, listed above, are also the indicators of which patients will do well with treatment methods that aim to develop insight. The difficulty in assessing the relative value of treatment techniques is notorious. Clinical experience suggests that psychoanalysis, as the most extensive and profound of the therapeutic measures, is most likely to make permanent changes for the better in both the symptoms and the personality structure of patients who need techniques involving insight. Good and lasting results, however, may be effected with less protracted methods, and success has been reported with the techniques of hypnoanalysis. It should be mentioned here that the removal of symptoms by hypnotic suggestion has little value. Either the symptoms return after a brief period or others appear in their stead; at the same time, such symptom removal may lead to the development of distressing anxiety or depression.

Psychoanalysis. In the history of the development of modern psychotherapy, the conversion reaction holds a central place, for it was with patients exhibiting this disorder that techniques of psychoanalysis that form the basis of much modern practice were first evolved. Indeed, it was believed for years that psychoanalysis or intensive long term dynamic psychotherapy derived from analysis was the specific treatment of choice for the conversion reaction. As knowledge of the psychological factors at work in conversion symptoms has increased and as the concept of the disorder has broadened, the therapeutic approach has also been modified. It is now apparent that only a portion of the total number of patients with conversion phenomena are candidates for psychoanalysis or modified techniques based on achieving insight. The remainder require some form of supportive psychotherapy.

Supportive therapy. Those patients who are not candidates for one of the insight psychotherapies are generally suffering from narcissistic character problems in addition to their conversion symptoms, with predominantly pregenital conflicts, particularly those centering around dependency needs. For such patients, supportive therapy is indicated. This may be a one-to-one relationship; it may be provided in a group therapy setting; or there may be a combination of both therapeutic approaches. Environmental manipulation is often an important and helpful measure and includes working with the patient's immediate family and other people close to him. Through such supportive techniques, a patient's symptoms may diminish markedly or even disappear, and he may begin to function more effectively in his daily life, maintaining the improvement as long as the supportive relationship remains intact.

Physical treatment. A number of physical treatment measures have been attempted and advocated, such as electroconvulsive therapy, various forms of leukotomies, and carbon dioxide inhalation; but there is little or no evidence to indicate that they have any lasting or basic effect on the disorder. More recently, conditioning therapy has been employed. This is an interesting approach, but it is too soon to know how effective it will prove to be; it remains still a technique for experimental investigation. Drug therapy is sometimes a useful adjunct to psychotherapy, especially if disabling anxiety is present, but there is no direct pharmacological effect of any of the drugs in current use on the conversion symptom itself.

Prevention. Finally, a word must be said about the group of patients who develop conversion symptoms that complicate a physical bodily illness and lead to a psychogenic prolongation of the patient's disability. It is of interest to note that such individuals—no matter how incapacitated, infantile, demanding, and dependent they may be after they develop symptoms—have frequently been exceptionally hard-working, conscientious, self-sufficient, and independent people before their illness. Psychological observations reveal

that their behavior pattern before the onset of their illness represented, in part, at least, a reaction formation that kept underlying dependency needs out of the patient's awareness and under control. In many ways, surface behavior patterns had enabled the patient to lead an effective and socially useful life while he was well. At the same time, however, his personality organization made him vulnerable to serious psychological complications should he develop a physical illness. When he becomes sick or is injured, a psychological regression tends to occur. The dependency needs emerge in the patient's overt behavior, using the symptoms as a vehicle of expression. A new psychological equilibrium is established, and even though the physical lesion initially underlying the symptoms of the illness is healed or much improved, the symptoms remain in full force as a means of gratifying the dependency needs that have been grafted into them. Psychological invalidism has now replaced a physical illness.

It usually requires a period of time for this shift in equilibrium to take place, and the behavior of the people in the patient's environment can often play a large part in determining whether the shift that leads to the appearance of conversion symptoms will occur. If the professional personnel caring for the patient and his family force him into passivity and dependency by being overly solicitous and overly helpful, by unnecessarily restricting his activities, and by emphasizing the disability caused by his symptoms, they can often bring about or hasten the march to chronic psychological invalidism. If, however, from the start of the illness, they allow the patient as much freedom of action, autonomy, and independent self-sufficiency as the nature of the illness will permit; if they emphasize the positive capabilities that still remain to the patient despite his sickness; if, from the beginning, they help him focus his attention ahead to a return to self-sufficiency and encourage him constantly to increased independence as his physical disorder improves, then there is a good chance the patient will avoid a major and catastrophic regression. Once the equilibrium has shifted to produce psychological invalidism, it is often impossible to effect a change, and the condition becomes chronic. Prevention is essential if such conversion reactions are to be avoided, and prevention requires that the physician be aware that they occur and that he institute the measures appropriate to blocking their development.

Suggested Cross References

A more detailed discussion of psychoanalytic theoretical constructs, such as the psychosexual stages of development and the Oedipus complex, may be found in Mack and Semrad's chapter on classical psychoanalytic theory (Chapter 6), in Area C, on current theories of personality and psychopathology. In that same area, alternate viewpoints regarding personality development and family dynamics are presented in

the sections that deal with some of the other psychological schools of thought (Chapters 7 to 9). For additional comments regarding the relationship between conversion reactions and psychophysiological disorders, see Section 31.1. Kapp discusses psychogenic pain in Section 30.12. Further information regarding psychoanalysis and psychotherapy may be found in Stewart and Levine's section (Section 34.1) in Area G, on psychiatric treatment.

thesia), the dissociated experience of feelings without appropriate external or internal stimuli (as in hallucinations, *déjà vu*, and feelings of unreality), and certain episodes of unusual behavior seemingly beyond conscious control are appropriately classified as dissociative phenomena within the framework of modern dynamic psychopathology.

Pierre Janet introduced the concept of dissociation, and ever since there have been historical connections between dissociative reactions and conversion reactions under the general label of hysteria. There were also important historical relationships between dissociation and hypnotism, which played a key role in the evolution of contemporary psychodynamic concepts. The phenomenology of hypnosis and the classical psychopathology of hysteria must be held clearly in mind while considering dissociation, because all are undoubtedly manifestations of the same fundamental psychophysiological mechanisms. Additional connections will be found in considerations of epilepsy, which involves some similar problems of consciousness; of anxiety, which may provoke the increased exercise of dissociation as a psychodynamic defense mechanism in any given case regardless of diagnosis; and of schizophrenia, in which disturbances of association constitute an important and usually early component of symptomatology.

The basic theory of dissociation originated with Charcot's teaching in 1872 that the stream of consciousness breaks up into diverse elements in cases of hysteria. Janet's famous inquiries in 1889 into clinical instances of somnambulism and fugue, with their attendant amnesia, and his conception of dissociation of consciousness which went with it, were extended by the contributions of Morton Prince. Following a classic study of multiple personality in 1905, Prince went on to develop the concept of *coconsciousness* as comprising "conscious states that we are not aware of, simply because they are not in the focus of attention but in the fringe of the content of consciousness. The term would also include pathologically split off and independently acting coconscious ideas or systems of ideas such as occur in hysteria, reaching their apogee in conscious (multiple) personalities and in automatic writings."

Disagreements arose between Prince and Sigmund Freud, primarily in terms of defining the mechanisms whereby ideas could be held outside of awareness. As Freud put it,

Morton Prince...has objected to my explanation of the forgetting of dreams on the ground that the forgetting is only a special case of the amnesia attaching to dissociated mental states, that it is impossible to extend my explanation of this special amnesia to other types and that my explanation is consequently devoid of value even for its immediate purpose. His readers are thus reminded that in the course of all his descriptions of these dissociated states he has never attempted to discover a dynamic explanation of such phenomena. If he had, he would inevitably have found that repression (or, more precisely, the resistance created by it) is the cause both

23.3 DISSOCIATIVE REACTION

LOUIS JOLYON WEST, M.D.

History

The four classical dissociative reactions are fugue, amnesia, somnambulism, and multiple personality. However, the dissociation from awareness of sensations (as in conversion reactions and hypnotic anes-

of the dissociations and of the amnesia attaching to their psychical content.

Elsewhere Freud seemed to deal with some of the phenomenology of what Prince considered coconscious by employing the term "preconscious" for those latent ideas of relatively little strength. If they became sufficiently strong, they should have penetrated into consciousness; and if they did not so penetrate regardless of how strong they had become, they were considered to have been rendered more truly *unconscious* by the forces of repression. At that point the modern psychopathologist might consider such mental content, if it constituted a substantial component of personality function or content or experience, as dissociated. The resulting clinical symptomatic picture would be called a dissociative reaction.

Definition

The current edition of the American Psychiatric Association's *Diagnostic and Statistical Manual, Mental Disorders* gives the following description:

Dissociative reaction. This reaction represents a type of gross personality disorganization, the basis of which is a neurotic disturbance, although the diffuse dissociation seen in some cases may occasionally appear psychotic. The personality disorganization may result in aimless running or 'freezing.' The repressed impulse giving rise to the anxiety may be discharged by, or deflected into, various symptomatic expressions, such as depersonalization, dissociated personality, stupor, fugue, amnesia, dream state, somnambulism, etc. The diagnosis will specify symptomatic manifestations.

This definition is obviously a descriptive sketch of certain clinically observed behavioral manifestations commonly termed dissociative. Unfortunately it is neither complete nor clear. The reference to the repressed impulse being "discharged by, or deflected into, various symptomatic expressions..." is hardly an explication of dissociation as a mechanism of defense. To bring some order into an area that has long been confused, the following discussion of underlying biological and psychological considerations has been prepared, and a new classification of dissociative reactions has been derived from it.

Psychophysiological basis of dissociation. Although there are traditional definitions of dissociation as a mental mechanism, it has not been a lucid concept: it has tended to merge with repression or conversion or both. The formulation presented herewith considers dissociation in terms of information processing. If this is accepted, then a number of terms (dissociation, suppression, repression, coconscious, etc.) can be characterized as special instances of a general psychophysiological adaptive mechanism for dealing with information.

This master mechanism (or group of mechanisms) of the central nervous system is responsible simultaneously and continuously for (1) scanning and screening incoming information; (2) processing both new and old information in such a way as to modu-

late the state and content of conscious awareness; (3) integrating or associating new information with previously stored information; and (4) controlling information output in the form of behavioral responses.

In the past 10 years an increasing fund of data concerning the physiology of awareness has made it possible to conceptualize the clinical dissociative reactions as pathological exercises of these normal functions. Whatever one may choose to call the mechanisms involved (perhaps "integrative" would be an appropriate term), they subserve the requirements for scanning and screening information, modulating the sphere of awareness moment by moment, controlling the processes of associative thought, and relating mentation to action.

The student of brain function as information processing will wish to familiarize himself in a general way with the contributions of cybernetics. The extent to which electronic computers can be used as models for human brain activity has probably been overemphasized, but this nevertheless can be an instructive approach. If the basic differences between digital computers and analogue computers are first comprehended, the model (highly simplified) presented in Table I may then be useful to keep in mind.

Only a minute portion of total available information—from the external environment, from within the body, and from the brain's own enormous stores—can be held in awareness at any given time. Concentration, reality testing, and simple survival require the exercise of scanning and screening mechanisms to keep the searchlight of awareness focused on selected areas of psychic content and to keep everything else out of awareness. Because hypnosis has long been utilized as a laboratory technique to study this process, its relationship to dissociation is worthy of some consideration here.

Hypnosis has been defined by Weitzenhoffer as a "dissociation of awareness from the majority of sensory and even strictly neural events that are taking place." This definition implies an appreciation of the combined functions of focus and exclusion or of a balance between excitation and inhibition, which is shared by the psychoanalytic theories of hypnosis on the one hand and by Pavlovian theories on the other. But such a dissociation of awareness characterizes not only hypnosis but all the classical dissociative reactions as well. It also covers the more recently defined clinical dissociative phenomena, as well as dreams, hypnagogic states, sleep paralysis, highway hypnosis, trances and ecstasies in mystical and religious rites, fascination or fixation in flyers, daydreaming, and many other mental phenomena, including the exercise of normal concentration at all levels of intensity. In fact, the "majority of sensory and... neural events" are always excluded from consciousness at any given time in a normal person.

Apparently an optimal variety and intensity of sensory input are required to maintain the exercise

of the integrative mechanisms in relation to current external reality. In prolonged monotony, or in artificially produced sensory isolation, the diminished input of sensory information in the presence of continued alertness permits an increasing awareness of the brain's previously recorded perceptions. These, being released into consciousness and woven into scenes or invested with form and symbolic meaning by psychodynamic forces, are then perceived as images or hallucinations. During those periods of sleep in which cortical arousal increases (marked by rapid eye movements and emergent stage I electroencephalogram) paradoxically without increase in appreciation of environmental stimuli, a basically similar release phenomenon occurs, and dreaming takes place.

Hallucinations—the dissociated emergence of stored sensory information into awareness—thus occur normally during dreaming sleep. They can also occur during waking conditions when a similar disparity exists between cortical arousal and effective sensory input. Some examples include (1) fatigue of the sensory systems, as in sleep deprivation; (2) the blocking or poisoning of the sensory systems by certain drugs, such as lysergic acid diethylamide (LSD), which distort perception while simultaneously stimulating the diencephalic centers regulating arousal; (3) the differential chemical effect on sensory arousal systems in the person going into and coming out of gas anesthesia; (4) “jamming the circuits” of environmental contact as in panic reactions in combat or other severe stimulation from the environment causing information input overload; and (5) psychologically motivated dissociation, that is, the deliberate withdrawal from or narrowing of focus on the external sensory environment in the hypnotic subject or the mystic. Less deliberately the same thing can happen to the pilot fixated on his altimeter, the entranced driver on a superhighway who drives off the real road onto a hallucinated lane, the patient in a fugue state, or the hallucinating schizophrenic patient.

In these examples, the information-processing paradigm permits the establishment of a logical relationship among hallucinations occurring under a variety of conditions, including dissociated states.

Neurophysiological substrate. Does the brain possess a system that permits an infinitely variable integration or modulation of incoming information on the one hand and awareness on the other? A structural basis for this function is known to exist. In 1942 Morison and Dempsey described a nonspecific thalamocortical projection system. This was followed in 1949 by the classic paper of Moruzzi and Magoun, defining some of the functions of the ascending reticular activating system. At about the same time Jasper noted the relationship of the thalamic reticular formation to the previously described thalamocortical projection system. Further discussions by Magoun, Liv-

TABLE I
Information Processing in the Human Brain

Constant integration of and feedback between these two ongoing information-processing activities is a necessary component of normal personality functioning. Superego activity would exemplify this. So too would the constant expression of appropriate affect, the attachment of accurate meaning to new experiences, and the undistorted recall of past events in their total significance to the individual.

Primarily Analogue Information Processing	Primarily Digital Information Processing
1. Paleocortical structures and connections (limbic system, visceral brain)	1. Neocortical structures and connections (cerebral hemispheres)
2. Largely preconscious or unconscious	2. More available to consciousness
3. Emotions, feelings, affective state	3. Reality testing, ideas, systematic thought
4. Intuitive—“all or none”	4. Rational—“shades of gray”
5. Nonverbal	5. Verbal
6. Illogical, hard to modify	6. Logical, subject to modification
7. Provides emotional meaning and flavor	7. Provides objective meaning and prediction
8. “Primary process thinking” (Freud)	8. “Secondary process thinking” (Freud)
9. Largely affected by id influences	9. Largely affected by ego functions

ington, Lindsley, MacLean, Hernandez-Peón, and others clarified many of the regulating functions subserved by the ascending reticular activating system. It soon became apparent that the integrating effects of this extraordinary network involve not only sensory information and arousal or alertness but also emotions, memories, and transactions between neocortical and paleocortical structures.

Reticular activating system. At the present time it seems fair to say that the ascending reticular activating system integrates and modulates the relationship between incoming sensory information and awareness. Together with the diffuse thalamocortical projection system, it permits both general arousal and attention to discrete stimuli. Furthermore, feedback systems from the cortex, both stimulatory and inhibitory, have recently been described. Finally, the reticular system now proves to be both ascending and descending, activating and inhibiting, integrating and isolating. The differential functioning that is presently known to be possible within the total activity of the reticular formation—whereby stimulation, inhibition, arousal, and depression can be reciprocally exercised simultaneously in different areas—makes it possible to comprehend the anatomic basis for the screening and scanning functions that must exist.

Since the first papers on the ascending reticular activating system in the unanesthetized brain began to come from Magoun's laboratories, much sub-

sequent information has been compiled about the activities and interrelationships of the reticular formation to clarify how it subserves the reality-testing functions of the ego. When there occurs a marked narrowing of the focus of awareness on a particular aspect of reality, to the exclusion of much of the rest, as in the initiation of the hypnotic trance, then sensory data (verbal suggestions) taken in through an open channel (rapport) become effective because they are not subjected to ordinary reality testing.

The reticular system will maintain arousal while simultaneously inhibiting appreciation of an unusual proportion of reality under two natural circumstances that can be demonstrated in normal hypnotic subjects. The first circumstance is one in which attention is fixed by a narrow range of stimuli, monotonously presented. The relatively gradual but definitely progressive decrease in reactivity to other stimuli under these circumstances can be demonstrated behaviorally in man as well as in lower animals under certain conditions. The second circumstance under which the reticular activating system functions in this manner is in the presence of information input overload. When arousal is already high—because of strong emotion or vigorous stimulation or both simultaneously via several sensory modalities—feedback mechanisms cause the functional nonacceptance of nearly all additional incoming information, regardless of its significance under ordinary conditions of adaptation.

The experienced hypnotist recognizes these two psychophysiological situations as the most probable concomitants for the two characteristic clinical conditions in which hypnosis may be easily induced: the gentle, monotonous, object-focused laboratory technique on the one hand; and the emotion-laden, high stimulus input stage technique on the other. The first is near the hypnagogic point with a low level of arousal but an even lower level of effective input; the second is under conditions of great arousal and impaired information processing because of input overload's figuratively jamming the circuits. Such circumstances are also likely to permit the emergence of spontaneously occurring dissociative phenomena, for example, a mystical experience during reverie in a monotonous environment under the first set of conditions; a sense of unreality and partial amnesia for events occurring while participating in a riot under the second set of conditions.

Between these two extremes, at the point of maximum conscious influence on reticular formation activity through postural factors, choice of surroundings, etc., deliberate exclusion of external stimuli may be achieved through intense concentration. It is probably in this way that trained hypnotic subjects and mystics enter the trance state deliberately.

Since the normally operative associative and integrative functions subserved by the ascending reticular activity system are probably fundamental to hyp-

nosis, the continuity of hypnotic and dissociative states with normal states of concentration is easily seen. A normal state of concentration can blend into the dissociative phenomena that sometimes accompany hypnagogic reverie or day-dreaming on one extreme and agitated arousal on the other. Thus it is not surprising that older reports of normal waking electroencephalographic (EEG) tracings of patients in hypnotic and dissociated trance states have been modified by the more recent discovery of both hyperarousal patterns and sleeplike patterns on the EEG under certain conditions of hypnosis and in the midst of dissociative reactions in patients. Since it is not only the absolute state of arousal of the individual but also the relationship between level of arousal and effective information input that is significant in defining the state of consciousness at any given time, one can comprehend the manifestation of dissociative phenomena under a variety of electroencephalographic conditions. One can also understand differences in autonomic responses to stimuli, and in subjective appreciation of stimuli, by individuals in states of dissociation.

The foregoing frame of reference should permit a better understanding of the relationship between the actions of various drugs and the induction or resolution of dissociated states. No drug can be evaluated for its effects in relation to dissociation without our first considering the psychophysiological state of the subject at the time. Some subjects, being just right for the induction of hypnosis, enter a trance easily, without the use of drugs. A drug administered under these circumstances—for example, thiopental (sodium Pentothal) given intravenously to a soldier with an acute dissociative reaction in combat—may appear to be quite effective in producing an abreaction and bringing the patient into contact (narcosynthesis) when in actuality hypnosis is an important component of the maneuver.

The patient who is chronically anxious may be rendered distinctly more accessible to hypnosis by the use of a drug that decreases central autonomic reactivity while maintaining a good cortical arousal pattern. This is borne out by the fact that phenothiazine derivatives can be helpful in such cases, whereas phenobarbital, which depresses arousal, is usually not helpful. On the other hand, in a very tense patient, with manifestations chiefly in the musculoskeletal system, a barbiturate or meprobamate may be helpful in inducing hypnosis. Although such stimulants as amphetamine and methylphenidate have seemed to make hypnosis more difficult in certain patients, they may help, when combined with short-acting barbiturates, to ease the induction of hypnosis in certain agitated, depressed persons.

If hypnosis is seen as a controlled dissociated state, or as a special state of concentration maintained through the integrative mechanisms mediated by the reticular system, it might be expected that drugs that cause spontaneous, pathological, dissociative phenomena to appear would at the same time render difficult or impossible the maintenance of a hypnotic trance. This is likely to be true, for example, with LSD. The subject under its influence may be more or less suggestible, but hypnotic rapport is likely to be tenuous. On the other hand, suggestions made prior to the administration of LSD appear greatly to influence the subjective response to the drug. Indeed, suggestions of benefit may be responsible for much of the therapeutic or psychedelic effect it produces in certain cases.

Psychodynamics. In the clinical dissociative reactions, the mechanism whereby information is patho-

logically deflected from the main psychic organization involves forces that are basically meaningful and understandable in psychodynamic terms. In other words, the process of dissociation occurs in the service of defending the ego against material that is perceived as dangerous on a conscious or (more often) an unconscious level. This usually comes about in a time of particular crisis. Maturational shortcomings, emotional conflicts, and stressful life situation are then superimposed upon each other to create a trap or impasse that cannot be resolved by the patient because of overwhelming anxiety inherent in the available possible solutions. The resolution brought about by the dissociative reaction, handicapping or crippling through it may be, nevertheless produces a change for the better (i.e., more comfortable) at some level in the psychological economy of the individual. Thus the symptom may resist treatment until the special concatenation of forces that produced it can be altered.

Symptoms. To unravel the psychodynamic puzzle that underlies each case of dissociative reaction—in other words, to comprehend the pathogenesis of the illness—it is helpful for the physician to ask himself three questions about the symptom itself.

Primary and secondary gains. What does the patient gain by his symptom? The primary gain will usually be best formulated in terms of anxiety reduction. This anxiety is not ordinary conscious fear; it is based upon inner conflicts about which the patient is quite unaware. Thus in a case of amnesic flight from a combat situation (described below under "Fugue"), the soldier's conflict arose out of unconscious homosexual feelings toward a comrade, coupled with death wishes toward him as a source of deeply threatening stimulation. When the comrade was killed in action, the soldier was stricken with guilt at having magically brought about the secretly desired murder, which also served as a sacrifice whereby he himself was spared from death. For this a terrible retribution would be visited upon him unless he could escape it. Under conditions where ego function was impaired by fatigue, sleep loss, conscious rational fear of the enemy, and depression over the loss of his friend, the episode of dissociated wandering behavior (fugue) occurred. This contained elements of a search for the lost object and also took the patient away from a situation in which (at the level of unconscious, primary process thinking) it seemed that his own violent destructive impulses would bring death to those he loved.

The secondary gain is frequently obvious to the clinician (e.g., the soldier's actual escape from the dangerous front lines) but may be obscure. Often it can be formulated in terms of attention getting, avoidance of an unpleasant situation, satisfaction of passive needs, financial benefits (no matter how slight, cf. compensation neurosis), face saving, or the

perpetuation of newfound gratifications in the sick role.

Symbolism. What does this particular symptom symbolize or represent? This may have meaning of a different sort. The soldier chose a symptom that could be seen as a journey in search of something or someone lost and also in flight from the intolerable. But why did he not fall into a trance? Or develop blindness? Or have an "accidental" self-inflicted injury? Inquiry along these lines will always prove to be instructive.

Timing. Why does the symptom appear now? Important clues to pathogenesis always turn up in answer to this query. Significant prognostic implications are also found here. The nature of precipitating factors must be delineated psychodynamically from predisposing factors. For example, military psychiatry's well known "3-day schizophrenia" (which is perhaps better defined as a dissociative reaction in the form of a frenzy or delirium) characteristically occurs only *after* the soldier has been removed from combat and is on his way home; cases studied while returning by slow boat from combat in Korea revealed clearly the dynamic significance of real and fantasied problems to be faced back home as precipitating factors. Such factors are obviously of quite different significance from those of symptomatically similar breakdowns called "combat exhaustion" at the front.

Predisposing personality characteristics. The development of dissociative symptomatology takes place in the presence of predisposing personality characteristics that lend form to the symptomatology. These characteristics will be understood in each individual only through consideration of biological, developmental, interpersonal, and sociocultural factors involved in his character formation, his ego structure, the effectiveness of his other mental mechanisms, and the over-all assessment of his personal liabilities and assets.

Generally speaking, however, the premorbid personality of patients clinically diagnosed as suffering from dissociative reactions will reveal emotional immaturity, self-centeredness, an historical likelihood of episodic emotional disturbances in childhood or adolescence, and a remarkable lack of solidly gratifying or mutually supportive interpersonal relationships. Criteria may be present which make it possible to classify such predisposed individuals as possessing schizoid, passive-dependent, or inadequate personalities. Others may meet the criteria for so-called hysterical or compulsive characters, who develop dissociative syndromes upon becoming psychologically decompensated under stress from within, without, or both.

Basic conflict. The foregoing information, regarding symptomatology on the one hand and predisposition on the other, represents a converging double path-

way to the central issue or psychodynamic core of the illness: namely, the basic unconscious conflict that is generating sufficient anxiety to require the emergency misapplication of information-processing mechanisms (i.e., dissociation) in the service of psychic homeostasis. The nature of such conflicts is discussed elsewhere in detail. However, factors to be considered must include the characteristics of unacceptable or repressed impulses involved, the state of their repression, and the experiential basis upon which they are so dreadfully unacceptable or dangerous to the individual. In addition the clinician will want to understand situational factors that are intensifying the conflict by stimulating the strength of the repressed impulse, or by weakening the present state of defense against it, or by generating a new but related conflict that will upset the existing state of equilibrium.

Summary. With the foregoing orientation, it is reasonable to define dissociation as a psychophysiological process whereby information—incoming, stored, or outgoing—is actively deflected from integration with its usual or expected associations.

A dissociative reaction can then be defined as a state of experience or behavior wherein dissociation produces a discernible alteration in a person's thoughts, feelings, or actions, so that for a period of time certain information is not associated or integrated with other information as it normally or logically would be.

Such an experience may or may not be considered psychopathological. If it is, arbitrary clinical criteria decide whether it will be diagnosed in terms of its own characteristics (in which case it will be called a dissociative reaction) or whether it will be characterized as part of the symptomatology of another syndrome, such as schizophrenia or hysteria, in which it is involved.

Clinical Description

The comprehensive model of dissociation discussed above can be used to classify a variety of human experiences, roughly progressing in each category from phenomena common in everyday life to those seen in severe psychiatric illnesses (see the outline below). The items marked with an asterisk (*) in the outline below are discussed as clinical dissociative reactions in the text. The others either are not best defined as illnesses, or are dealt with elsewhere under the discussion of psychodynamics or as significant aspects of other clinical entities such as conversion reaction or schizophrenia.

I. Dissociation of incoming information

A. From part of the environment

1. Selective inattention
2. Hypnotic anesthesia
3. Hysterical anesthesia (usually involving a limited area of the body or one sensory modality)
4. Anesthesias in the psychoses (often associated with self-mutilation)

B. From the environment as a whole

1. Concentration, day-dreaming, brown study, reverie
2. Distraction or highly focused attention (for example, analgesia of injured athlete or wounded soldier while caught up in the excitement of the moment; pain threshold of normal subjects can be elevated 40 per cent by simple distraction)
3. Hypnotic trance (open channel or rapport with hypnotist is usually retained; if rapport is lost, hypnosis may become a dissociative trance state)
- *4. Dissociative trance states (psychogenic stupor, twilight state, dream state)
- *5. Other trancelike states (highway hypnosis, fixation or fascination in flyers, self-induced trances by mystics and fakirs, trances in religious ecstasy or frenzy)
- *6. Somnambulistic trance

II. Dissociation of certain portions of stored information (memory and/or sensibility) from the remainder

A. Suppression (information is deliberately put out of awareness)

B. Repression (stored information that should be possible to call to awareness cannot be recalled)

C. Dreams and hallucinations (stored portions of information, being processed in a preconscious stream, emerge into awareness and are experienced as though they were incoming information)

*D. Estrangements and paramnesias (feelings of unreality or estrangement, derealization, depersonalization, *déjà vu*, *déjà entendu*, *déjà fait*, *déjà pensé*, cosmic consciousness, *Weltschmerz*, etc.)

*E. Amnesia (psychogenic)

*F. Multiple personality

III. Dissociation of output—actions or behavior (often accompanied by elements of I and II)

A. Inhibition or blocking of output: briefly, under stress ("freezing"); of a motor function (conversion reactions of paralysis, aphonia, etc.); of the entire body (catatonia); in episodes (catalepsy); in attacks (cataplexy).

*B. Parapraxes, psychogenic tics, motor automatisms

*C. Automatic writing

*D. Ganser syndrome

*E. Dissociated experiences related to sleep (for example, sleep paralysis, sleep-talking, sleep-walking, enuresis in adults, somnolentia, sleep hallucinations)

*F. Fugue

*G. Frenzied or violent states of dissociated behavior (amok, berserk, latah, arctic hysteria, pathological intoxication, dissociative delirium, hysterical fit)

Dissociative trance states. These have been called twilight states, dream states, psychogenic stupors, etc. In general, they are characterized by marked unresponsiveness to the environment, a considerable degree of immobility, and an apparent total focus of attention on something deep within the self or far out in the cosmos. The trance may last for an hour or for days. It is characterized by relatively sudden onset (usually in a life situation involving considerable stress), a dazed or dreamlike quality, and total or partial amnesia on being restored to contact with the environment. There are various degrees of both

immobility and detachment. In some cases the patient may go through the motions of daily routine but seem to be much detached, hazy, vague, preoccupied, or apathetic. When the condition immediately follows some traumatic event, the patient is often described as shocked or stunned.

An 18-year-old girl at a sorority party was hypnotized by an amateur, who told her to cut off her hair with an imaginary pair of scissors. Facing the mirror, she went so far as to raise her hand to her head. Then she suddenly began to weep and struggle. She was helped to a chair, where she soon subsided into a trance, staring off into the distance and ignoring the frightened hypnotist's pleas to wake up. She was taken to the student health service, where a small amount of intravenous sodium amobarbital (Amytal) was injected. An abreaction occurred in which a childhood experience, involving punishment for cutting her own hair, was partially relived. More amobarbital was given, sufficient to induce sleep. Upon awakening, she was amnesic for the entire period. She was rehypnotized by a psychiatrist who took pains to dispel any untoward suggestive residues, following which she completely recovered and experienced no further difficulty.

A 24-year-old graduate student in philosophy was working long and hard on research for his thesis, which involved a complex and abstract combination of mathematical and philosophical propositions. Although he seemed somewhat preoccupied and withdrawn, nothing remarkable was noted until one evening his roommate discovered him staring out the window. He did not respond to questions or physical prodding, including well meant face slapping and a glass of cold water poured over his head. He could be made to get up and walk around, but he would not disrobe for bed. His roommate was able to lead him to a coffee shop, where he sat for a while and eventually sipped a little coffee, but he was still mute and dazed. The condition lasted for about 48 hours. Subsequently, there was vague recall of portions of this experience, in which the patient reported elaborate dreamlike fantasies and thoughts but only the most tenuous awareness of interactions with the environment.

Other trancelike states. In a variety of environmental circumstances, individuals with a relatively normal psychic life may be drawn into dissociative reactions with trancelike characteristics. Usually the induction of such states involves prolonged and unusual concentration on a task, an object, or a situation; the rest of the environment is either blandly monotonous or so distracting as to require being screened out of awareness by prolonged concentration. The characteristics of such trances are infinitely variable, depending on social, cultural, and individual circumstances.

Highway hypnosis. This condition is responsible for many accidents, some of them fatal, and is well known to experts in highway safety. Accidents caused by highway hypnosis can be distinguished from those that come about when someone actually dozes at the wheel. (The latter situation produces a characteristic pattern of weaving on and off the road, skid marks when the brakes are finally applied abruptly after the victim is jolted awake, etc.) In highway hypnosis the individual becomes entranced and loses track of the passage of time and even of place. He may retain sufficient contact with the environment to drive

safely, only to discover when he emerges from his reverie that he has gone perhaps 30 miles past his destination, driving right through the town without having realized it. In more profound cases, the trance state may lead to immobilization at the wheel, or the road ahead may be a hallucinated straight one where the real one curves, in which case the driver may steer straight to his doom. Highway hypnosis is likely to occur on long, monotonous stretches of modern turnpikes, where there are few challenges requiring the motorist to pay significant attention to what he's about.

Fixation or fascination. This is a related trance-like condition, not uncommon in people who work where they are forced to focus on a given object for prolonged periods of time or with great concentration under stress. It is of particular interest in aviation medicine because of the great danger to pilots who become entranced. The flier may fix his attention on one instrument in the panel while flying at night or in deep fog; he may lose track of time, distance, fuel, or the requirement to turn back before heading too far out to sea. Fighter pilots in training have become fixated in the process of aiming at a target and been unable to pull away, crashing straight into it.

In some instances under conditions of prolonged monotony, hallucinations may occur. One airman saw little green men with rucksacks on their backs marching across the instrument panel. Many pilots have experienced kinesthetic hallucinations under conditions of prolonged, monotonous flight. At such times, there is the sudden and unshakable sense that the aircraft has markedly altered course, that it is diving, that it is upside down, or that it is otherwise out of control. In such cases, old "seat of the pants" pilots have been known to ignore the evidence of the instrument panel in order to take disastrous "corrective" action. More than one flier has prepared to bail out of an aircraft that he felt was out of control when in fact it was flying straight and level. These kinesthetic hallucinations have sometimes been incorrectly termed vertigo by flight surgeons. They are easily distinguished from true vertigo by history alone.

Self-induced trances. For thousands of years men have apparently been aware of the possibility of inducing trance states in themselves, with or without the use of drugs. Characteristically, the Eastern mystic achieves the desired effect by undertaking a posture (such as the lotus position) that promotes immobility, and by concentrating, either inwardly behind closed lids or outwardly on some object such as a pool of ink, a ball of crystal, or a religious icon. In time, depending on the degree of skill acquired and the expectation and prior preparation of the individual, there is a complete withdrawal of awareness of the environment and a sense of transportation into another mental sphere. A state of ecstasy or beatitude

may be experienced if the trance brings with it a sought for sense of oneness with the universe or closeness to the deity.

Such trances may be entered into by people who are in motion, particularly if they are engaged in some monotonous activity—rhythmical clapping at a revival meeting, ritual dancing in a tribal ceremony—in which case the typical loss of contact with the environment occurs, the movements take on an automatic quality, and often some type of climax, with or without sexual overtones, is experienced. Characteristically, the individual who emerges from such a state recalls little or nothing of what went on around him during it but may give a vivid report of his subjective dreamlike or ecstatic experience.

Somnambulistic trance. Children frequently walk in their sleep, usually to the bathroom or in what appears to be some nonspecific searching behavior. However, it now seems likely that a differentiation should be made between sleep-walking behavior (discussed below as a dissociative experience related to sleep) and somnambulistic trance. In the latter, the patient carries out an elaborate series of actions having great psychological significance while he is in a trance so deep that the bystander deems him to be out of contact with the environment in the same way that a sleeping person is. Shakespeare's *Lady Macbeth*, whose eyes were open though their sense was shut, did not see her watchful lady in waiting and anxious physician, but nightly relived in detail the murder of Duncan and verbalized her own guilty musings.

The classic cases of somnambulism studied by Janet were characterized by elaborate nocturnal dissociated states in which highly complex activities of great meaning to the individual were repeated almost identically in episode after episode. It now appears most useful to define such dissociative reactions as somnambulistic trances, probably representing a relatively well organized or encapsulated partial abreaction of a significant experience, rather than the physical acting out of a dream. From a physiological standpoint, dreams probably cannot be acted out, because most human dreams are accompanied by profound generalized inhibition of the voluntary musculature (even though specific small groups like the extraocular muscles may be active).

A 30-year-old male sergeant in the Army had been experiencing a number of marital problems while living off-post. He finally left his wife and children and moved into the barracks. One of the major conflicts in the marriage stemmed from his preoccupation with his automobile and his insistence on tinkering with it during his free time rather than providing companionship for his family. After the separation on a number of occasions he got up during the night in the barracks, went to his foot locker, took out some tools and proceeded to dismantle his bunk as though it were an automobile. Usually he would stack the parts neatly in a corner, find an empty bunk. Each operation took about an hour. During these periods he seemed asleep or totally out of contact with the environment, although his eyes were half open. On one or two occasions, when

irritated barracks mates attempted to interfere or waken him, he lashed out at them in a strenuous and frightening way, so that subsequently they left him alone. On being ordered to consult the psychiatrist about his behavior, he told of the episodes as they had been described to him, but he denied any memory of them and was quite sheepish and embarrassed about what had been taking place.

Estrangements and paramnesias. Estrangement is a sense of detachment, disengagement, or loss of usual connection with places, persons, situations, or concepts. The usual or expected relationship is not sensed; a strange feeling—or lack of feeling—takes its place. Estrangement and paramnesia are closely related. Paramnesias are distortions of memory which are often accompanied by strange feelings of such intensity that they would be considered hallucinations of sensibility. Paramnesia is often experienced in dreams, and the paramnesic patient may be unsure whether certain things really happened to him or whether he merely dreamed they happened. Estrangements and paramnesias are frequent complaints among epileptics and early schizophrenics, and in chronic anxiety syndromes.

Feelings of unreality. These mild estrangements are not uncommon when, during some life crisis, an individual suddenly feels that a process in which he is involved is somehow unreal, strange, or not truly happening. This may be accompanied by an auto-scopic sensation (as though one were standing outside oneself and watching what is going on) or by a feeling that events are taking place in some automatic fashion without volition or control on anyone's part, or that the entire experience is a dream from which one will shortly awaken. Such estrangements are commonly brief and related to considerable degrees of stress. If prolonged, they tend to shift into derealization or depersonalization.

Derealization. This is a sense that one's surroundings have changed and that the real environment is in some significant way no longer what it used to be. The change may seem threatening to a greater or lesser degree. It may involve only the immediate situation, or it may be on a global basis. It may compromise interpersonal relationships, physical surroundings, or both. Often the patient will agree that there are no objective facts to substantiate his sense of environmental estrangement, yet he cannot shake off the feeling. In some instances the sensation is only fleeting or, if prolonged, relatively mild. At other times it is very marked and persistent, in which case it may progress into delusional thinking (especially of being influenced).

Depersonalization. In this state there is a sense of estrangement from one's self. This is usually experienced as a loss of identity or of one's own reality. The physical body may seem altered or be experienced as though it belonged to somebody else. There may be a sense of transmutation of one's corporal substance, so that it seems to be made of a different material than before—much heavier, much lighter, or

of a different texture—the parts perhaps uncoordinated or peculiar in relationship to each other. The sense of timing may be affected, so that motion seems mechanical or unpredictable. A sense of altered somatic sensibility may play a role so that the world is seen as though one's eyes had telescopes for lenses, or touch muted as though one were wrapped in cotton.

In other cases the emphasis is not so much on the physical self as on the identity or self-image. Here the sense of change is more difficult for the patient to define. He feels altered, modified, transformed, or sometimes (like the man becoming a cockroach in the early stages of Franz Kafka's *Metamorphosis*) as though he were in the process of changing into something different, unknown, and usually undesirable.

Déjà vu. This might be termed an illusory or hallucinatory sensation of familiarity. It is experienced by the individual who comes into a place or situation that objectively is strange or new to him, but who suddenly feels the powerful and distinct impression that he has been there before or has had the identical experience some time in the past. *Déjà vu* may be evoked by meeting a person, as in the well known song "Where or When." Generally it is experienced in relation to the visual impression of a total situation. Marcel Proust's masterpiece, *Remembrance of Things Past*, emphasized the way that some isolated perception, perhaps scarcely appreciated (an aroma, a breath of wind, a fragment of a song), could bring a whole experience rushing back. Freud believed that *déjà vu* is essentially a dissociative phenomenon, but the association transpires without the individual being aware of the stimulus. Thus the resultant recollection (repressed) is at an unconscious level, and all one consciously experiences is the sense of familiarity that would normally have been associated with it but is here dissociated. Another way of considering the phenomenon is that repression of the Proustian recollection is only partial, the digital portion being held unconscious while the analogue component breaks through and is experienced alone.

Déjà entendu is a variant of the above, particularly related to the impression that what one is hearing at the moment has been heard before. It is usually evoked by spoken words.

Déjà fait is another variant, having to do with the specific sense that what is happening to one has happened before.

Déjà pensé is a particularly interesting phenomenon in which one is certain that one has already thought of a matter or had an idea, or possessed a specific bit of knowledge, which is in fact new. This not uncommon paramnesia may be responsible for the widespread belief in prescience—that is, the ability to know ahead of time that something is going to happen. Frequently it develops that an individual is convinced he has had a prescient experience because,

when a certain event transpired, he had the distinct feeling that he already knew it would take place.

Déjà raconté is still another variant in which the individual feels that he has been told before of an experience from the remote past when he is, in fact, hearing it recounted for the first time.

Déjà voulu is a slightly different manifestation in which the individual feels that something he now desires is exactly the same desire that he felt at some previous time.

Jamais vu. The opposite of *déjà vu* is sometimes called *jamais vu*. Here someone looks on a familiar sight only to find to his astonishment that it seems strange, as though he had never seen it before. This is probably best considered an estrangement related to derealization.

Cosmic consciousness or illumination. Not all spontaneous dissociative experiences are unpleasant. With no apparent cause, one may experience a sense of fabulous joy and well-being, in which all the emotions that go with delightful discovery, profound insight, and a sense of immortality are rolled into one. Various drugs may precipitate such reactions; LSD is only one example. Related to states of ecstasy or dissociation involving religious experience of other varieties as described by William James, cosmic consciousness is of special interest to psychiatry because it was defined by a prominent 19th century psychiatrist, Dr. Richard M. Bucke, in a remarkable book, *Cosmic Consciousness*. Since its publication in 1901 this work has undergone some 22 editions, the latest in 1964. Bucke's great experience occurred in 1872, when he was 35 years old, while he was walking home after a halcyon evening's discussion of poetry with some friends. He was thinking of nothing special when suddenly he felt an overwhelming state of happiness, comprehension, universal understanding, and love, accompanied by a sense of being enveloped or illuminated by an extraordinary rosy light. In his magnum opus, Bucke presented evidence of similar experiences in the lives of a number of people, including Gautama, Socrates, St. Paul, Francis Bacon, Pascal, Spinoza, and Blake, as well as many of his own contemporaries, particularly his idol, Walt Whitman. Needless to say, Bucke did not define the experience as a dissociative reaction. His whole subsequent life was affected by it; he considered it to be a phenomenon of both religious and Darwinian evolutionary significance.

Weltschmerz. This may occur—and often does to college students and young adults—with the same sense of sudden cosmic awareness as Bucke's illumination, but the emotional accompaniment is one of exquisite sadness, futility, a sense of the incredible smallness of man in the universe, the inevitable existential pain of the world, and the suffering inherent in the human condition.

Amnesia. A circumscribed or catathymic amnesia for the events that transpired during the attack is

typical of the classical major dissociative reactions. However, the patient who is diagnosed primarily as a case of amnesia usually gives *present* loss of memory and often of identity as a chief complaint. Characteristically, he is discovered in a daze, unable to account for himself, to tell where he came from, or sometimes even to give his own name.

A 34-year-old civilian air traffic control specialist with considerable experience in directing landings under direct vision was transferred from the tower to the radar control room to work on blind ground-controlled approach procedures monitored by radar. He was made very anxious by this situation, in which he felt an excessive degree of responsibility, and had many unexpressed doubts about the effectiveness of the equipment, the methods, and himself. Shortly thereafter a fatal aircraft accident occurred while he was on duty and responsible for the landing procedure. Preliminary investigation suggested that pilot error was to blame. However, a formal hearing was scheduled, in which the patient was to give testimony. Two days later he most uncharacteristically failed to report to work, although his wife said he had left home as usual, seeming only a little preoccupied. After 24 hours he turned up at the city hospital under the guidance of a policeman. He seemed dazed and confused and was unable to identify himself. He described a total loss of memory. Investigation revealed that on the way to work he had been involved in a very minor traffic accident, in which he bumped into the car ahead of him. Both automobiles were traveling slowly at the time, and the patient had exchanged the usual information although there was no visible damage to either vehicle or driver. Apparently he then placed his wallet in the glove compartment of his car and wandered off from it in a state of amnesia, which gripped him for about 72 hours. Upon recovering, following an Amytal interview in the hospital, he was unable to account for anything that happened during the 3-day interval; the last thing he recalled was the traffic accident.

Multiple personality. In reviewing the clinically documented cases of multiple personality, Abse was recently able to identify some 200 accounts. New cases are always turning up and have a particular fascination because of their dramatic characteristics. Fiction is replete with spectacular examples of more than one personality inhabiting the same body. Perhaps the best known is Robert Louis Stevenson's *Dr. Jekyll and Mr. Hyde*. A whimsical counterpart was Mark Twain's *Pudd'nhead Wilson*, a character derived from an even funnier version, *The Remarkable Twins*, in which the hero actually has two heads with distinct personalities that alternate in their control of the individual's total behavior. A recent case history, *The Three Faces of Eve*, was made into a successful motion picture.

Clinically there is a considerable degree of variation from one patient with multiple personality to another. In cases of *dual* or *alternating personality*, two relatively distinct personality systems seem to exist in the same individual, autonomous from each other. Their dominance over the behavioral pattern alternates in time for periods ranging from hours to years. While the first personality predominates there is no awareness of the existence of the second; there is amnesia for any previous period in which the second personality was temporarily in control; the two per-

sonalities are always quite different from each other. As a rule, the original personality tends to be somewhat shy, inhibited, timid, and conscience-ridden; the second one, which usually emerges for the first time at a significant moment in the individual's life, is likely to be bolder, more outgoing, and much less inhibited. Usually he has amnesia for the life of the original personality, or evolves a fictional previous history of his own.

In other cases of multiple personality the original or dominant ego is somewhat more mature, although still substantially handicapped in some area of emotional development. The additional or subordinate personalities, two or even three of which may appear successively in the course of treatment, are usually aware of the first or "host" personality and have comments to make about him. But the original personality remains unaware of his intrapsychic stowaways and is amnesic for events that take place during the period that a subordinate personality has been in control.

Clearly, the psychopathology in multiple personality can shade over into other dissociative categories. The diagnosis will depend on the predominant characteristics of the reaction. Amnesia is by definition an established part of the condition. In fact, every case of massive amnesia is in some ways a case of dual personality, but amnesia will be the basic complaint. If one of the personalities decides to escape from the situation in which the previous personality has been living, his flight may partake of some of the typical qualities of a fugue. In the patient with a fugue, the episode of amnesia is obviously related to the flight and the necessity for it. In typical cases of multiple personality the alternate or subordinate identities carry out their activities in the same community, there is no flight, and current amnesia is not a complaint.

James was a highly conscientious, religious, shy, quiet, well-mannered bookkeeper, last seen by the janitor of his office building when he departed after working (typically) until 10 o'clock at night. When he did not appear for several days his wife, having checked with several relatives, informed the police. However, in spite of the usual search, no trace was found of James.

Two years later in the same city a friend of the family noticed a laborer riding on a bus and identified him as the missing person. She spoke to him, and he seemed surprised that she knew his last name; he gave his first name as Jim. She told him that his parents and wife were looking for him; he was amused and assured her that he had no relatives in town. However, she persisted, so together they went to the police station, where identification was made on the basis of fingerprints. The man was referred to the Veterans Administration hospital for study. Jim gave a history (quite vague up until 2 years before) that was similar in some ways and quite different in other ways from that of James. During the previous two years Jim had earned his living as a construction worker. He had also been a miner, a cowboy, and had performed other kinds of manual labor. He was rugged, sexually aggressive and promiscuous, generally good-natured, a free spender, and an atheist. His reappearance in his home town had, he insisted, been only by accident because he had heard there was work available there.

Contact was made with James, the original personality, through hypnosis; the dynamic circumstances surrounding the take-over by Jim were then identified. James had felt frustrated, trapped, defeated, hopelessly tied down by forces and commitments with which he could not cope. His choice of occupation had been forced on him by a dominating mother. His wife had voiced numerous complaints about him, including reflections on his manhood, and had flaunted her extramarital activities before him. The demands of his employer he felt were excessive, and yet he had no way of refusing to meet them. James' last memory was of a sense of mounting panic and despair on the night of the disappearance.

Here is a rather typical example of dual personality in which elements of fugue played a role at the onset. In a characteristic way Jim gradually built up a confabulated past in which he came to believe. In other cases men have developed an elaborate new life and a very convincing past history, have settled in a new place, and have sometimes started a new family without legally disposing of the old, for which they have no memory. Such cases periodically come to light; neither the old wife nor the new can believe that the man they know is capable of bigamy. Unlike the heroes of "The Remarkable Mr. Pennypacker" and "Captain's Paradise," the patient with dual personality appears to have no awareness that he has led what might be termed a double life. Almost never does one of the subdominant identities of the rapidly shifting variety of multiple personality undertake to marry or make other legal commitments, although sexual acting out, gambling, and minor antisocial acts are not uncommon.

Beatrice was a single, 32-year-old school teacher who lived alone and was considered to be prim, proper, colorless, and a premature old maid. She sought psychotherapy because of blackouts and headaches associated with them. For some time it was difficult to clarify what these episodes actually constituted. However, psychotherapy of a relatively nondirective type was initiated. One day, half way through a rather dreary interview, in which the patient tonelessly described her unwavering admiration for her strong-minded, dominating mother, she suddenly sat up in the chair, turned a bright glance on the doctor, laughed flirtatiously, and said, "Doc, how long are you going to put up with such a square?" This was Trixie. On a number of occasions when Beatrice retired early with a sick headache, Trixie had bounded out of bed an hour later, dressed in high style, and gone out on the town. She drank, picked up men in bars, frequented dance halls, and attended racy movies. She was contemptuous of Beatrice, who remained unaware of Trixie's existence through months of therapy.

A third personality, Bea, began to emerge after about a year. Bea and Trixie knew about Beatrice and each other. They struggled for control for a while. Finally Bea, a relatively mature type with some of the better characteristics of both of the others, predominated. Gradually the others faded out of the picture. The patient and therapist agreed that Beatrice was no great loss; however, they both had moments when they missed the naughty but vivacious Trixie.

Parapraxes, psychogenic tics and motor automatisms. A parapraxis is a dissociated action that serves no useful purpose. Parapraxes often occur outside of awareness and are related to the seemingly more conscious but uncontrollable twitches and spasms of

psychogenic tics, and also to the apparently voluntary but tenacious habitual motor automatisms.

Freud's discerning inspection of many specific examples of parapraxes in everyday life—such as a slip of the tongue or pen, a small accident, or the misplacing of an article, without the individual being aware of the idea associated with the action—contributed significantly to the evolution of his understanding of unconscious mental processes.

Most psychogenic tics are brief, recurrent, seemingly inappropriate and more or less uncontrollable movements, which range from the almost unnoticeable to the overtly grotesque. In the patient's life such movements were apparently once associated with an emotional experience at a crucial time, but now appear either as a substitute for the emotion (thus unconsciously manifesting it) or as its equivalent (thus warding it off). A tic or involuntary grimace which includes head turning, eye closing, and the raising of a shoulder may be the interminable repetition of a wince elicited by a face-slapping episode in childhood, now appearing as a dissociated movement the unconscious purpose of which is to diminish anxiety. Many types of psychogenic tics or habit spasms have been described and must be differentiated from those related to encephalitic or other neurological disorders. Torticollis, which may be more or less tic-like, is an example of borderline diagnostic problem of this type.

There are many other dissociated actions which serve no obvious purpose, which often occur without the individual's awareness and even contrary to his desire, and which (at least in a number of documented instances) contain manifestations of some encapsulated, repressed emotional conflict surrounding a traumatic episode or situation from earlier experience. Some of these are called "automatisms" and constitute rather elaborate and often constantly repeated movements (or verbalizations) over which the patient seemingly has no control. Severe instances may be seen in clinical schizophrenic or dissociative reactions. Milder forms are often called "motor habits" (ear pulling, hair twisting, eye winking, etc.) and are very common in less disturbed patients and in clinically normal people. Such motor habits can be controlled to a greater or lesser extent but tend to become worse when the individual is tense and anxious or when his attention is distracted from conscious efforts to control the movements.

Automatic writing. Of considerable historical interest, both in medicine and in fiction (for example, *The Beast with Five Fingers*) automatic writing is seldom seen in this day of typewriter and dictating machine. However, it is still useful to look for it. Frequently such behavior can be elicited in the examination of a patient in a dissociative trance state. He may be mute and seem to be out of contact with reality. However, if a pencil is put in his hand, with a piece of paper under it, he may begin to write. A

functioning component of his personality actually contacts the examiner and enables some sort of an interview to take place. This can sometimes be accomplished even with a patient in catatonic stupor. The automatic writing is not always responsive to influence from without. It may occur spontaneously and may seem quite irrational or indecipherable. Yet it can be of great value in unraveling the psychodynamic conundrum that constitutes the genesis of the patient's condition.

Ganser syndrome. Sometimes called "the nonsense syndrome," this is frequently seen among prisoners or other individuals who may at first seem to be faking or pretending to be mentally ill. The patient characteristically makes elaborately wrong but not totally irrelevant responses to whatever instructions he is given. Calculations may be all slightly off, for example, 2 plus 2 is 5, 3 plus 3 is 7, 15 plus 15 is 31. When asked in the clinic if he knows where he is, the patient says, "I'm in a ball park" and then adds, "but I ain't having a ball." In the neurological examination he says that his toe is being pulled up when it is actually being pulled down and vice versa; he calls the percussion hammer a saw, identifies the doctor as a nurse, etc.

Formerly considered to be an elaborate type of malingering, the Ganser syndrome is now generally recognized as a psychopathological entity. Even when the patient keeps a portion of his consciousness aware of an intent to deceive, he always turns out to be psychiatrically much sicker than he thought he was while "deceiving" the jailers or the doctors.

Dissociative experiences related to sleep

Sleep paralysis. This condition is characterized by total inability to move the body while in a state of relative mental alertness and orientation, on awakening from sleep. It usually lasts for only a brief period of time (seconds to minutes), but the patient feels as though it will never end. Here the total capacity for bodily movement is dissociated from the usual volitional controls. The extent to which psychophysiological factors involved in sleep and wakefulness may be involved in episodes of sleep paralysis is unclear. It may be that for some reason spontaneous waking occurs during fast wave (rapid eye movement or dreaming) sleep. Ordinarily, this is the time of sleep in which the most profound muscular relaxation of the entire body obtains; the mechanisms whereby this is effected may still be at work for a while after the onset of conscious awareness of surroundings by the sleeper.

Sleep paralysis is frequently but not necessarily associated with narcolepsy. There have not been systematic studies sufficient to gain any good idea of its incidence or of its degree of correlation with other dissociative symptoms in the same person. There may be more than one attack in a single night, or episodes may occur months or even years apart.

Dr. P. was a 35-year-old surgeon. One evening, while discussing the day's work in a social setting, a psychiatrist mentioned to him with pleasure that another case of sleep paralysis had been found for a series that was being collected. The surgeon expressed curiosity and inquired about the symptoms. When he learned what they were, he burst into tears. He then gave a story of having suffered from the condition for years. He thought it was a form of epilepsy and was desperately keeping it a secret for fear that he would have to give up surgery. Meanwhile he had been taking a combination of anti-convulsant drugs to ward off the possibility of a grand mal attack, and dextroamphetamine to maintain alertness for his work.

His episodes were fairly typical. He would awaken at night, become aware of his surroundings, and find himself unable to move. Lying in bed, he would desperately attempt to sit up or even turn over, to no avail. A sense of panic and entrapment would grow. Finally, it would reach a point that he was able to cry out. As soon as this happened, he would recover the ability to move.

Following this disclosure, an electroencephalogram was carried out, and the results proved to be normal. All medication was discontinued. Simple reassurances brought a major degree of relief, although the episodes continued to occur from time to time. Since he was resistant to the idea of psychotherapy, no effort was made to explore psychodynamic factors, which appeared to be related to rather significant unconscious passive strivings.

Sleep-talking and sleep-walking. Normal phenomena occurring during sleep in children may persist into adolescence and adulthood as a manifestation of a poorly understood lack of maturation of the nervous system. There is probably a difference between normally occurring sleep-talking, or gross bodily movements during sleep, and dissociated states that appear similar to them. In normal people, sleep-talking is mostly incomprehensible mumbling, with an occasional word or phrase that can be understood. It occurs not during dreams but during slow wave sleep, when the characteristic rapid eye movements and rapid low voltage EEG of dreaming are definitely not present. Sleep-walking has been studied by Kales et al., in subjects (responders to an advertisement for sleep-walkers) whose electroencephalograms and electro-oculograms were monitored. Many elaborate nocturnal movements, including some that involved actually getting up out of bed and stumbling around, took place during a slow wave sleep. These were apparently nonpurposive wanderings, and the subjects seemed capable of endangering or injuring themselves by falling or bumping into objects.

These cases are obviously different in many ways from the somnambulistic trances of Janet, or the case described earlier. The former type of patient probably actually awakens and then enters a trance which is called somnambulistic because it is profound, self-limited, and nocturnal. They may lie in bed and carry on elaborate conversations for which they subsequently have no memory but which otherwise display all the characteristics of communication during hypnosis. If he walks, the patient in a somnambulistic trance arises in a clear cut episode from his bed. He is not like a child groping his way to the bathroom

and stumbling over objects, nor like those adults who seem to arise in some kind of a confused state during slow wave sleep when it is quite possible that they may fall, injure themselves, or engage in nonpurposive behavior. Unlike such sleep-walkers, the dissociated somnambulist launches into involved, complicated, and highly meaningful activity, which on numerous subsequent occasions can be observed to occur again and again in very much the same pattern.

Thus it appears that between normal sleep-talking and bodily movements on one hand, and clear cut trance behavior or dissociated somnambulism on the other, some varieties of sleep-walking and -talking exist as dissociative phenomena related to sleep in ways not yet fully understood (Kales et al.).

Enuresis. In young children, enuresis occurs during the deepest period of slow wave sleep, usually prior to, and perhaps in some way as a substitute for, the first dream of the night. The idea that such a child is somehow unconsciously electing to pour out his hostility toward his parents in this fashion is not borne out by the electroencephalographic facts. However, in cases where enuresis persists into adolescence there are conflicting data.

Some adolescents and young adults have been observed who become (bioelectrically speaking) awake but who lie quietly in bed as though in a trance, empty their bladders, and then return to physiological sleep. Such episodes usually occur after 5 or 6 hours of normal sleep. These cases may manifest various criteria to substantiate a diagnosis of dissociative reaction; if so, they can be treated successfully and even dramatically. They must be distinguished from those borderline cases where the bed wetting represents some type of maturational failure of the nervous system, urological disease, or perhaps even nocturnal seizures.

Somnolentia or sleep drunkenness. This condition in adults seems to be a dissociative persistent manifestation of night terrors in children. In somnolentia the patient seems to be neither asleep nor awake, is characteristically disoriented, and to a greater or lesser extent reacts to nightmarish mental content, sometimes becoming frenzied or violent.

Sleep hallucinations. In addition to the hallucinatory experiences of normal dreams there are other circumstances in which hallucinations occur in relation to sleep. Some of these are common in normal people and are generally called hypnagogic hallucinations; they are usually visual but may be auditory or kinesthetic; they may occur while falling asleep (in the hypnagogic state) or while awakening (in the hypnopompic state). Usually these hallucinations are experienced very briefly during a momentary transitional period between sleep and wakefulness. However they may endure for a longer period or come during the night, constituting definite episodes in which the patient struggles to terminate the hallu-

cinosis by "waking up" but cannot do so. Such attacks of sleep hallucinations are very similar in some ways to sleep paralysis. They are subjectively quite different from dreams, in that the patient is partially aware of his real surroundings, like Dickens' Scrooge during his conversation with Marley's ghost.

Fugue. The element that characterizes fugue most clearly is flight, usually entered into rather abruptly. From a stressful life situation, the individual wanders off, perhaps in a daze or confused mental state, often with a complete amnesia, sometimes without care for his person or for his surroundings. In more elaborate fugue states, where the element of acute trauma is not as great a precipitating factor, the patient may function for days or weeks in a seemingly normal way. However, the thing that characterizes him during this period is that he is traveling. He may come to himself spontaneously with no awareness of how he got where he is.

A 19-year-old infantryman was found wandering across the countryside far from the battlefield by the military police. He appeared to be dazed and could not identify himself or his organization. It developed that he had been on the front line under fire for approximately 10 days. One afternoon, in the midst of a bombardment, when every sensible soldier was crouched in a foxhole or dugout, the patient suddenly jumped out of his trench and began to walk away, heedless of the shouts of his comrades or of the shrapnel flying through the air.

Seen at the division hospital, he was found to be suffering from no physical injury. A sodium Pentothal interview produced a marked abreaction, in which the significant element was not so much fear of death as it was guilt over the death of a comrade who had gone on a patrol in the patient's place. After 72 hours of constant, heavy sedation, he awakened to express a sense of surprise at his surroundings and a desire to rejoin his unit. He was amnesic for the fugue. After another 2 days of observation he was permitted to return to his outfit, and he served without incident throughout the rest of the campaign.

Jack Smith, a seedy looking dishwasher in an Oklahoma hamburger joint, surprised his employer and customers by walking out of the kitchen and saying, in cultivated tones, "Where am I and what am I doing here?" Seemingly a drifter, he had wandered in several days before and had been employed out of pity. He identified himself as Ronald Worthington M., a Methodist minister from Massachusetts. He had no recollection of how he had made his way to Oklahoma, nor could he recall anything that had transpired during the previous 6 weeks.

A psychiatric study revealed a variety of personal and professional conflicts in his life immediately prior to the onset of the fugue. He had apparently hitchhiked halfway across the country, stopping from time to time to work at odd jobs as Jack (the name of a handyman who had worked for his grandfather 30 years before). He gained a little preliminary insight into the nature of his reaction and undertook to obtain definitive psychotherapy upon returning with mixed feelings to his congregation, his wife, and his mother-in-law.

Frenzied or violent states of dissociated behavior. These occur as acute dissociative reactions under a wide variety of circumstances and cultural settings. They are of sudden onset, brief duration, and abrupt termination with amnesia for most if not all of the

attack. The episodes contain elements of violent, frenzied, outlandish or wildly bizarre behavior. They must be differentiated from temporal lobe seizures.

Amok, berserk, latah. "Running amok" among the Malays is a state in which a previously normal person suddenly becomes violent, characteristically seizing a knife or some other weapon and raging through the village, attacking people at random until exhausted, overcome by force, or killed. In our own culture there are many situations in which individuals suddenly become violent, attacking others in a state of frenzy and great emotional display, for which the term "amuck" is used. Characteristically, the patient experiences amnesia for the episode, which frequently is found to be related to some immensely frustrating life situation in which he feels hopelessly trapped. Although such frenzies are not necessarily homicidal or suicidal, it is possible for an individual under these circumstances to injure others or himself.

Berserk or "going berserk" is a term often used synonymously with amuck as a state of violent rage or frenzy. It was originally applied to certain Nordic warriors (Barsarkers) who intoxicated themselves prior to battle by eating psychogenic mushrooms. Latah, a brief frenzied state among Malayan women, was compared by Wengroke with amok and with Arctic hysteria; all are culturally defined behavioral abnormalities that appear to meet our domestic criteria for acute dissociative reactions. There are undoubtedly many other varieties of dissociative behavior reaction, differing widely in relation to the particular culture of the patient.

Pathological intoxication. This is usually classified under alcoholism. However, many cases of pathological intoxication are probably acute dissociative reactions precipitated in predisposed persons by relatively small amounts of alcohol. Characteristically, the syndrome includes a rather abrupt onset, an impairment of consciousness, and a variety of psychopathological manifestations, including violent behavior. Such episodes are of uncertain duration, lasting from 1 to 36 hours, usually followed by sleep or stupor, following which there is typically an amnesia for the experience.

Dissociative delirium. This is a reaction similar to pathological intoxication but with typical symptoms of florid psychopathology, including hallucinations, wild emotional outpourings, and seemingly uncontrolled release of primary process material, with a certain amount of agitation, but not characterized by dangerous violence. It may occur as a pure dissociative reaction in response to emotional stress without any known biological precipitating factors; or some relatively minor change in brain function, such as the administration of a simple sedative in modest dosage, may play a role in bringing on the attack.

Hysterical fit. This old-fashioned term is still sometimes used to describe dissociative reactions in

which the patient is "seized" to act out, in an elaborate and dramatic fashion, some complex and prolonged fantasies, during which there is apparent loss of contact with the environment and a marked emotional display with a strong histrionic flavor. Such displays frequently include coital movements. It was perhaps on this basis that the reactions were classically described as hysterical fits or convulsions. Slight degrees of brain damage sometimes found in these patients are probably best viewed as contributing to the predisposition toward dissociative reaction, rather than as directly causative of the fits.

Diagnosis, Prognosis, and Treatment

The dissociative reactions are generally held to be primarily psychogenic in origin and psychoneurotic in character. However, there are areas in which they merge with certain types of seizure disorder, intoxication, behavior disorder, or psychosis. Differential diagnosis can be very difficult but should be possible in most instances.

The presence of brain damage does not mean that a bona fide dissociative or conversion reaction may not also be present and vice versa. Many clinicians believe that there is a substantially higher than chance relationship here, even though the nature of the brain disorder may vary widely, and the degree of impairment may range from gross to minimal. Temporary minor alterations in the state of the brain—such as those produced by fever, sodium amobarbital, other barbiturates, gas anesthesia, alcohol, or psychogenic drugs—may release the manifestations of dissociative phenomena where the propensity is strong. Even natural changes in brain function, such as those occurring in relation to the sleep cycle, may serve to permit dissociative behavior to emerge.

Since dissociative phenomena are likely to increase in the face of mounting anxiety, such symptoms frequently occur during the early stages of a schizophrenic illness. It is important that the differential diagnosis be made in such instances because the approach to treatment will be affected. Acute dissociative reactions may be difficult to distinguish from acute psychotic (catatonic or manic) syndromes. Yet careful observation of the psychopathology, a good history, and close observation of the patient over a period of time under treatment, will usually clarify the issue. Dissociative phenomena may be seen in a wide variety of diagnostic categories, ranging from epilepsy to schizophrenia. This should not prevent the clinician from making the diagnosis of psychoneurosis, dissociative reaction, when the clinical findings warrant it.

A note concerning medicolegal problems raised by certain dissociative reactions is in order. Is the undivorced remarried man with dual personality and amnesia a bigamist? Is the patient in a seemingly brief psychotic episode during a dissociative frenzy or pathological intoxication criminally responsible?

Is the soldier with fugue a deserter? Since dissociative reaction is classified as a psychoneurosis, the courts have often held such patients fully responsible. Each case will of course be tried on its merits. However, a good rule of thumb for the clinician called upon to give an opinion should be this: let the psychopathology at the time of the alleged offense determine the medicolegal opinion. Unquestionably some circumscribed psychotic reactions are dissociated, in the sense that they represent a break with a relatively integrated personality functioning before and after the episode. However, this leaves some important problems unsolved. A murderous episode of the type called "catathymic crisis" by Wertham may be all or partly dissociated. What is society to do with such a murderer, who has recovered his sanity before he even comes to trial? Is he guilty? Is he committable? And even the rule of thumb noted above is hard to apply usefully to the problem of the dual personality. Here is an area worthy of considerable attention by the forensic psychiatrist.

Prognosis of the dissociative reactions, like the other psychoneuroses, must be individualized in terms of motivation, age, intelligence, ego structure, characterological factors, duration of illness, secondary gains, etc. As a rule the prognosis for the acute attack or episode is good; the long term outlook is only fair and perhaps guarded.

The approach to treatment of the dissociative reactions is primarily that of a dynamically oriented psychotherapy that carefully takes into account the significance of unconscious factors, makes note of the predominating mental mechanisms at work, utilizes and to some degree analyzes transference and counter-transference factors in the doctor-patient relationship, and generally works toward the development of a greater degree of emotional maturity in the patient. Special techniques, such as hypnosis and narcoanalysis, can be employed if rapid relief of symptoms is desired.

By and large, the discussions of diagnosis, prognosis, and treatment in the chapter on conversion reaction apply equally well to dissociative reaction.

Suggested Cross References

For a discussion of the mental mechanism of dissociation on a psychodynamic level of description, the reader is referred to Mack and Semrad's section on psychoanalysis (Section 6.1). In addition, see Nemiah's section on the closely related disorder, conversion reaction (Section 23.2). Fundamental neurophysiological considerations may be found in Sections 2.5 to 2.9 on neuroanatomy and neurophysiology in Area B, on the basic behavioral sciences. That same area also contains sections on sensory deprivation, sleep and dreams, and hallucinogens (Sections 5.5, 2.4, and 5.4, respectively). Hypnosis is discussed in greater detail by Spiegel in Section 34.4, in Area G, on psychiatric treatment. Some of the disorders men-

tioned in this section, such as amok, berserk, and latah, are more fully described in Lehmann's section on unusual psychiatric disorders not included in American Psychiatric Association's nomenclature (Section 32.1). Enuresis is described by Pierce in Section 40.5, in Area H, on child psychiatry, and pathological intoxication by Chafetz in Section 27.3 on alcoholism.

23.4 PHOBIC REACTION

SHERVERT H. FRAZIER, M.D.

ARTHUR C. CARR, Ph.D.

Definition

The diagnostic designation phobic reaction is reserved for those disorders in which a phobia is the predominant symptom and in which reality testing is generally intact. As a disorder in which there is neither gross distortion of external reality nor evidence of structural or organic change, the phobic reaction is technically classified under the heading of psychoneurotic disorders.

The disorder was formerly classified as anxiety

hysteria, and the current designation reflects much terminological confusion, resulting partly from the distinction between *symptom* and *syndrome*.

Complicating the issue is a general imprecision of language that pervades the field. For example, the expression "phobic reaction" is sometimes used in a less technical sense than that of a diagnostic designation to mean simply that the patient is reacting with—that is, that he has—a phobia. Adding to the confusion engendered by this unfortunate usage of the word "phobic" are such expressions as "phobic object," "phobic situation," "phobic companion," and "phobic fear." This use of the adjective may be misleading, since in the real sense it is the person who becomes phobic, not the object, situation, companion, or fear.

As a symptom, a phobia may occur in a variety of psychiatric syndromes, appearing in a hierarchy of many other symptoms. In fact, phobias are most frequently found to coexist with other clinical signs—hysterical, depressive, obsessive-compulsive, and paranoid. Although these signs differ in relative importance from one disorder to another, there may be less justification for conceiving of phobias as comprising an isolated diagnostic entity than is implied by the designation "phobic reaction." In fact, many authorities tend to avoid using phobic reaction as a diagnostic classification, viewing phobias rather as symptoms that are superimposed on or extensions of other, more basic personality configurations or reactions.

Although this section follows the *Standard Nomenclature* of the American Psychiatric Association, (A.P.A.), the discussion herein generally applies to any clinically manifest and pronounced phobia, whether or not close examination supports a diagnosis of phobic reaction in the strictest technical sense. In the phobias discussed, the patient usually realizes the irrationality of his fear but feels compelled to avoid those situations that expose him to intolerable feelings of anxiety.

History

Since phobias of mild intensity are rather frequent phenomena in fairly normal adults and often occur in young children, it seems reasonable to assume that prehistoric man, too, was at times the victim of phobias. One of the earliest case histories of a phobic patient is attributed to Hippocrates. Shakespeare appears to have been referring to phobic people in *The Merchant of Venice*, when he wrote, "Some, that are mad if they behold a cat." Nevertheless, it was not before the middle of the 19th century that the term "phobia" is reported to have appeared in the psychiatric literature. Prior to that time, irrational fears were given little specific attention and were generally subsumed as aspects of other disorders.

In 1872, Westphal published a report on three male patients with fears of open or public places, a condition which is labeled "agoraphobia." His monograph played an important role in isolating the specific

reaction that today is labeled "phobic." Among other early psychiatric contributions to the study of phobic reactions are the writings of Kraepelin, Hall and Janet. But nevertheless, present psychodynamic conceptions of phobic reactions stem from Freud's clinical study, "Analysis of a Phobia in a Five-Year-Old-Boy."

This 1909 classic case was of "Little Hans," who refused to go into the street for fear that a horse would bite him. Freud's interpretation, based primarily on the father's account of the boy's behavior, suggested an exceedingly complex structure behind the phobia, basic to which was an intense fear of punishment (castration) stemming from unconscious hostility toward the father and a competition with the father for the mother's attentions, which were imbued with strong sexual overtones. According to Freud, Hans, by displacing his fear and anxiety from his father to the horse, could thereby both avoid the object of his phobia and love his father.

Subsequently, important work has been contributed by Arieti, Deutsch, Fenichel, Lewin, Ovesey, and Rado.

Epidemiology

There are no adequate data available on the epidemiology of the phobic reaction. Sound epidemiological data on any psychic disorder are difficult to obtain. It is particularly difficult in such a disorder as the phobic reaction, where the distinction between symptom and syndrome has not been consistently maintained. In addition, some classificatory systems, unlike A.P.A. nomenclature, give no special designation to even pronounced phobias.

In a report on characteristics of diagnosed patients of out-patient psychiatric clinics in the United States, the National Institute of Mental Health has reported the data which is extracted in Table I. Although such data must be accepted with some reservations, they nevertheless support the general impression that phobic reactions and phobias are more frequent both in the young and in females, and that the diagnosis of phobic reaction is not frequently made in clinical practice. Other studies report approximately similar percentages for the frequency of phobic reactions in the adult psychoneurotic population.

Evidence suggests a much greater frequency of phobias as a discrete psychiatric complaint than as a syndrome. Some psychiatrists feel that irrational fears of some kind are probably present in most psychiatric patients. On the basis of a standardized interview schedule, Spitzer reported unpublished data indicating that about 20 per cent of patients from a variety of psychiatric institutions give evidence of some kind of phobia, a finding consistent with other estimates.

Although Spitzer's data confirmed impressions that there is no relationship between the frequency of phobias and social class, the varying range in different settings (9 to 28 per cent) suggests that other cultural differences may influence the incidence of phobias. For example, contrary to other symptoma-

tology, significantly fewer phobias were found in patients from a rural area of Kentucky than from New York City, representing differences that could not be accounted for on the basis of social class or degree of communication difficulty. If such differences are confirmed and clarified through the increasing interest in the epidemiology of all psychic disorders, they may elucidate further the psychogenesis of phobias and the phobic reaction.

Reports invariably stress the naiveté and emotional immaturity of phobic patients, but many reports have indicated that the patients are of generally average or above average intelligence. Hence, there is no evidence to suggest that intellectual deficit is related to the phobic reaction. Likewise, it does not appear at present that religion or racial background significantly affects the incidence of phobias.

Etiology

The phobic reaction is closely allied to other psychoneurotic disorders, particularly that of anxiety reaction, in that its chief characteristic is anxiety—the affective state characterized by feelings of apprehension, uncertainty, and helplessness. Diffuse anxiety is usually present preceding the first occasion on which anxiety becomes focused on a specific object or situation. Thus, anxiety is prevalent both in the overt manifestations and in the genesis of the phobic reaction.

Source of anxiety. Although theoretical concepts of the primal source of the anxiety vary, many authorities feel that birth is the prototype of all later traumatic and anxiety-producing situations. However, the disorders referred to as “anxiety,” “phobic,” and “conversion” reactions were traditionally viewed as defenses against genital, oedipal impulses, which do not become prominent in the young child until the ages of 3 to 5 years. Indeed, the precipitating incidents in these reactions often do appear to be generally sexual in nature, but more recent concepts of anxiety suggest that all anxiety reactions in some way signify a threat of loss of love and support, a threat originally associated with the mothering figure. Consistent with this view is the observation that patients suffering from these disorders invariably manifest strong dependency problems, suggesting that anxieties already existed in the mother-child relationship prior to the period at which genital and oedipal impulses first appeared.

Little Hans appeared to be very preoccupied with sex and to fear punishment (castration) by his father. But authorities who believe that the primal source of anxiety is the separation from the mother emphasize the dependency aspects of Hans' problem and suggest that, for the total sequence to have occurred, the mother-child relationship must have been disrupted prior to the emergence of the boy's sexual preoccupation. It is significant that it was the mother who first threatened Hans with castration when she found him touching his penis at age 3½. His relationship with his mother had also been jeopardized by the arrival of a baby sister, of whom he was

TABLE I

Phobic Patients of Out-Patient Psychiatric Clinics

The figures given refer to patients for whom services were terminated in 933 out-patient clinics in the United States during 1961.

	Males under 18	Females under 18	Males over 18	Females over 18
Total patients.....	38,463	18,869	33,046	44,966
Psychoneurotic disorders..	3,618	2,277	6,543	14,302
Phobic reactions.....	343	319	169	452
Percentage of total disorders	0.9	1.7	0.5	1.0
Percentage of psychoneurotic disorders....	9.5	14.0	2.6	3.2

jealous. As in other clinical studies of phobic reactions, the consistent appearance of strong motivations for dependency gratifications seems to militate against the adequacy of any theory that emphasizes solely the role of oedipal or sexual impulses.

A characteristic of any anxiety reaction from the psychodynamic viewpoint is that something in the present precipitates a response pattern that harks back to the time when the individual was relatively helpless. In this sense only, anxiety is irrational, since the response to the current precipitating situation becomes inappropriately or disproportionately intense by association with memories or conflicts of the past. A reaction is elicited by the present situation which reactivates childhood fears of loss of love, of separation, and of punishment, with accompanying feelings of helplessness.

Early anxiety experiences. The child has his first experience of anxiety in his initial attempts to deal with other people, in his attempts to handle his own impulses and feelings in relation to them. He may begin to feel he cannot survive when he becomes aware that his existence is dependent on the actions of someone over whom he may have relatively little control, and on whom he is dependent for love and support. It is postulated that the child at this time requires reassurance from the mothering person to alleviate the anxiety and fears about survival that, because of his helplessness, are realistic. To allay such anxiety and fear, the child comes in time to learn a set of rules of operation and various adaptive techniques that assure his survival by warding off the threat of either punishment or the loss of love from significant people in his life.

During the course of the infant's learning to adjust to his expanding awareness of the world about him, anxiety comes to have a very useful purpose as a reaction to something perceived, consciously or unconsciously, as a threat to the established sets of behavior he has developed. Such signal anxiety alerts the individual to initiate action that prevents his mode of operation from being disrupted. Within limits, signal anxiety is useful, since it serves as a

constant scanning mechanism to perceive threatening situations with great sensitivity.

Early childhood experiences may unduly perpetuate feelings of anxiety and helplessness. When support and security are not sufficient to allay the child's normal developing sense of insecurity and helplessness, misperceptions may lead to the distortion of all later relationships. Early fears of disapproval may be transferred from significant individuals, on whom the child is dependent for security, to their representatives in later life. Such distortion, as an expression of anxiety, gives rise to further anxiety.

Effects of anxiety. As a subjective feeling state, anxiety is exceedingly uncomfortable and often intolerable. With physiological manifestations similar to those of fear, it may arouse symptoms of a hyperactive sympathetic system that include perspiration, tremor, diarrhea, vomiting, and changes in pupillary response, heart beat, pulse rate, and respiration. Unlike fear, however, anxiety is experienced as an inexplicable pervasive feeling of impending disaster that is frequently described as, "I'm afraid but I don't know why," "I have a feeling that something is about to happen but I don't know what," "I feel as if I'm about to explode or burst," or "I feel I'm going to lose control." Implicit in these complaints is the feeling of uncertainty and helplessness that, in extreme form, may give rise to feelings of panic, dissolution of the self, and disorganized behavior.

Precipitating threat. The precipitating threat in an anxiety reaction usually arises in the patient's present relationships with other people. These relationships in some way jeopardize the set of operations that in the past have served to ward off punishment or the loss of love. The threat is frequently symbolic in nature, representing a danger not directly known to the patient. Unlike a fear reaction, in which the source of the danger is recognized and apparent, the feelings of apprehension that arise in an anxiety reaction often appear to be without adequate rationale or logical basis, particularly to the patient himself, whose sense of helplessness is thus intensified.

Any threat that jeopardizes the individual's established way of relating to others and that causes conflict in his own value system can give rise to anxiety. Superficially, it may appear that the kinds of situations that elicit such threats are legion, involving problems of disapproval, self-satisfaction, guilt, integrity, and self-sufficiency, which is the individual's need to maintain a certain image of himself. On closer inspection, these situations generally seem to have in common the emergence of unacceptable impulses related to sex or aggression, impulses that in childhood were met either by the threat of punishment or the loss of love.

Parenthetically, it might be noted that some authorities feel that sexual impulses have a more important role in phobic individuals of the hysterical personality type, who probably make up the majority

of individuals classified as having strictly phobic reactions in our present nosology. Concomitantly, these authorities assume that aggressive impulses have greater importance in individuals of the obsessive-compulsive or paranoid types, who may develop phobias in the context of a syndrome which is frequently classified as something other than phobic reaction in our present nosology. Certain phobias also seem more clearly related to one type of impulse than to another, although both are usually present to some degree. For example, fear of open places is usually revealed to be related to fear of sexual impulses, fear of knives to aggressive impulses. In either event, intensity of the anxiety does not appear to be related to the specificity of the impulse.

Repression. In individuals who are prone to anxiety attacks, unacceptable sexual and aggressive thoughts, feelings, and impulses are ordinarily excluded from conscious awareness through the process of repression. In repression, one simply fails to see, hear, or attend to threatening stimuli, whether they arise in terms of internal pressures (intolerable wishes, impulses, or ideas) or external threats (emanating more directly from other people). This process goes on unconsciously; the person is no more aware of repressing something than he is of forgetting something. Unlike material that is forgotten, however, repressed material continues to seek expression through derivative behavior that often takes the form of disruptive symptoms.

Repression is a ubiquitous defense in the sense that everyone expends some energy in keeping many unacceptable impulses and their derivatives out of conscious awareness. In some individuals, however, repression is found to be the primary and overriding aspect of defensive strategy. Although repression leaves the individual perennially immature, naive, and unreflective, it may work tolerably well in protecting the individual from experiencing excessive anxiety without resulting in gross distortion of reality. In certain situations, repression fails to serve this purpose, because of either the nature of the external threat or the nature of internal pressure arising from intolerable wishes. The failure of repression then gives rise to directly experienced anxiety and its physical manifestations.

Displacement and avoidance. The beginning of a phobia is usually an acute anxiety attack, indicating that some threatening impulse or feeling has been triggered by the environment. Because anxiety, like fear, precipitates a "fight or flight" reaction, the human organism attempts to develop defenses to protect itself. The first line of defense is invariably repression but this defense may fail to keep the threat sufficiently from awareness or the anxiety within tolerable limits. Displacement, the process by which an emotion or feeling is unconsciously transferred from its source to a more acceptable substitute, may then be added to

repression, a combination of defenses that leads to the development of a phobia.

By means of displacement, the individual combats his diffuse anxiety by binding it to a particular object or situation. The thinking behind this seems primitive indeed, but, as Arieti indicated, the process reflects a general principle operative in psychopathology: what cannot be sustained at an abstract level because it is so anxiety-provoking is concretized. In many instances, life is made more tolerable for the individual, since the specificity of the fear now makes it manageable through the process of avoidance.

Because he avoids the object or situation on which his anxiety has been focalized, the discomfort he experiences may be barely noticeable to himself or others. Sometimes he may be able to use avoidance in such a way that he himself remains fairly comfortable, but his relatives must assume the burden of his solution. In other instances, the necessity to use avoidance may lead the patient to great inconvenience and deprivation. However confining or restricting the phobia may become in life's experiences or opportunities, the individual has at least arrived at a solution that offers some escape from the intolerable effects of prolonged diffuse anxiety. Should displacement and avoidance fail to serve this purpose, leading to a recurrence of the original anxiety, the phobia may then be extended.

A woman had a subway phobia that began with an inability to ride an express train between two fairly distant locations. Gradually it developed that she would have to get off the train at each local stop, wait until her anxiety diminished, get on the next train, and get off again at the next stop until her destination was reached.

It may appear strange that the anxiety is displaced to objects of the nonhuman environment—to animals, objects, and things—rather than to other people, as in paranoid reactions. Contrasted with the paranoid's defenses, the defense of the phobic person may seem primitive in its apparent similarity to the child's animistic perception of the world as threatening and overwhelming. But the displacement represented in the phobia permits the maintenance of a degree of interpersonal relatedness generally not found in the paranoid. The assumption of the helpfulness and inherent goodness of other people and the implicit optimism regarding potential gratification of dependency needs form the bases for the relative effectiveness of psychotherapy with the phobic individual, as opposed to the paranoid.

In regard to the early experiences that may have set the model for the type of displacement occurring in a phobia, it is well to recall the nature of the distinctions the child must originally make in the process of establishing a sense of ego boundaries as he learns to differentiate the self from the nonself. He must learn to differentiate the self from the outside world, and from other humans. In addition, he must distinguish between the animate and the inanimate, and

between the human and the nonhuman. The management of children may confuse rather than facilitate these distinctions and may serve to perpetuate the animistic and fantastic beliefs that figure so prominently in children's stories, comics, and fairy tales. A recent publication by Searles reveals the degree to which even the normal adult is engaged throughout life in a struggle to differentiate himself from his nonhuman environment.

In the person who develops a phobic reaction, it can be assumed that under extreme anxiety such differentiation becomes defective and that a regressive identification with the feared object or situation takes place. It can also be assumed that the original identification was characterized by ambivalence, since the phobia generally evolves around things or situations that either directly or symbolically represent a source of earlier satisfaction and attraction as well as of threat, in fantasy if not in actuality. Like any neurotic symptom, every phobia can be viewed as representing a compromise between wish (temptation, gratification) and prohibition (threat, fear). For example, heights (and falling from them) literally and figuratively represent fears common to both child and adult, but they also represent powerful pleasures of flight and abandon that under certain conditions are found to be most enjoyable: playing, falling, and jumping games, diving, skiing, sailing, and falling in the moral sense (that is, sinning).

Choice of feared object. What determines the choice of the object to which displacement occurs? Different authorities stress somewhat different possibilities. Using experimental neurosis as an example, learning theorists stress simple associative learning as the basis for selection. Watson and Rayner in 1920 reported the frequently quoted case of "Little Albert," who was conditioned to a fear of rats by an experimenter who struck an iron bar behind the boy just as he was about to touch a rat. The boy's original fear of loud noises was transferred to the rat and even became generalized to other furry objects. In such instances, the role of fortuitous circumstances seems prominent, as presumably rats or furry objects embodied no special properties that predetermined the boy's responses. Related to this viewpoint, both Rado and Lief have stressed the sensory context in which the original anxiety reaction first occurred as providing the basis for the selection.

On the other hand, traditional psychoanalytic theory places significance on the meaning of the symbolic condensation presumably represented by the feared object. Consistent with this view, the specificity of the choice in some instances does appear to represent an exquisitely unique crystallization of all the important determinants of the phobia, including the predominant impulse or threat against which the phobia is a defense. Lewin has likened the process determining the specific phobia to that which occurs in the formation of manifest dream content, showing

the same overdetermination and other parallel phenomena, including traces of early experiences.

The choice of some feared objects can be given meaning in terms of contiguity and continuity.

A woman walking in the street experiences an acute panic about an impulse pertaining to unacceptable homosexual wishes. The fear may be displaced or pushed out of awareness by attaching the anxiety to some circumstance in the immediate environment, such as the street.

A patient had a sudden impulse to take a kitchen knife and stab her 3-year-old child, who was causing her concern and anxiety. At that time, a whistle on a passing train sounded. The patient became phobic about locomotive whistles.

The choice of the feared object sometimes appears to be explained by simple determinants of present association, as in the examples above; but frequently these determinants only describe the situation precipitating the phobia without fully explaining the total condensation involved in the selection of the particular object.

The phobia of being out in the rain was seemingly established in the context of an experience in which a child saw a man without a head walking in the rain (probably a man with a coat pulled over his head). Subsequent investigation of the earlier bathing practices in the family, however, confirmed the prediction that this was a family in which the child from an early age was bathed by being taken into each parent's shower. Therefore, the phobia about the rain was probably as much determined by unacceptable sexual impulses resulting from the family's bathing practices as by the frightening sight of a man without a head.

The true meaning of any symbol to a patient can be determined only by listening to the associations of the patient. Reports of dreams and other fantasy productions are also helpful. Although universally symbolic meanings for the common phobic objects may be suggested, these are not invariably valid. Elongated objects may symbolize the phallus; enclosed objects may symbolize the womb; animals may symbolize aggression. But, like other objects and situations, all these objects may have many other meanings. A fear of the street, for example, may symbolize fears of leaving home, sexual temptation, exhibitionistic impulses, or being attacked. On the whole, it is probably better not to approach the patient's phobia in terms of preconceived ideas about the symbolic meaning of specific objects and situations.

Clarification of the complex reasons for the choice of the specific feared object usually necessitates the patient's systematic recall of childhood experiences for which the phobic adult has long been amnesic. Even in successfully treated cases, however, one is sometimes not certain that all the determinants behind the symptom have been revealed; nor is this necessary, except as a matter of academic or theoretical interest. The inferential nature of the conclusions regarding any phobia is illustrated by the continued speculation regarding "Little Hans." To the already complicated structure that Freud hypothesized as underlying Hans'

phobia, some authors have suggested additional determinants, including a relation between the fact that at one point Hans' fear was transferred to a *white* horse exclusively and the fact that Hans' father was a physician. On the other hand, others disparage the assertion that Hans' phobia in any way symbolized a fear of his father and interpret Hans' phobia simply as a conditioned fear response with a sequence similar to that of the experimentally induced fear in "Little Albert."

Interpersonal aspects. In the discussion to this point, the major defenses leading to a phobia—repression, displacement, avoidance—have been dealt with largely as intrapsychic phenomena. In formulating the psychodynamics of the phobic reaction, some authorities stress more explicitly its interpersonal aspects in terms of the ongoing relationships the phobic person is experiencing with others. For example, phobic persons are frequently found to have convenient partners ("phobic companions"), who stand by continuously to prevent them from experiencing acute panic or anxiety. Such companions, often a husband or child, may become very dedicated, often finding secondary gain for themselves by becoming collaborators in a mutually reinforcing cycle.

A merchant with a fine store in a profitable business area had a wife who became phobic. He gave up his business and devoted all of his time to being with her. She would not let him out of her sight. If he walked the dog, she stood at the window to watch him so that he would not go beyond her view. Apart from financial difficulties because of his inability to work, he did not appear greatly concerned by this state of affairs; in fact, he seemed to take great satisfaction in being needed by his wife. It was not until he was called to leave the city to visit his sick mother that he expressed dissatisfaction with the conflicting demands on him.

Always present in a phobic person is an unconscious wish to be taken care of and to have his dependency needs satisfied. The phobic individual may use his companion as a symbolic parent—that is, as a "good mother," who will protect him from his fears. He may also use the companion as a "bad mother"; by keeping the companion with him, he is reassured that his aggressive impulses will be neither acted upon nor thought about. Some phobic patients keep a companion to protect themselves from acting out other forbidden impulses, as if the companion lessened the necessity for watching over their own impulses. In a sense, this maneuver is based on the feeling that "You can't lose control if there is somebody present who will manage you."

Phobias can be used aggressively to control others and gain special privileges. There are some cases reported in which the need for a companion is motivated by the desire to disengage the companion from some other relationship that the phobic person resents. A phobic girl, for example, by requiring her mother to be constantly at her side, assures herself that her mother and father cannot be alone together. A situation that guarantees exclusive possession is thus created. In most instances, the relationship between

patient and companion is one of mutual intimidation and satisfaction. The companion may find excessive gratification in the phobic person's behavior, thus being reluctant to give up a source of his own pleasure.

Patient history. In patients who develop phobic reactions, some common elements are often discernible. Frequently there is evidence that the person simply never succeeded in mastering early childhood problems. Every child, in the course of development, must learn an appropriate method of dealing with impulses of sex and aggression, that is, self-assertion. The anxiety accompanying these impulses may produce a guilt-ridden, fearful child who is particularly apprehensive about parental retaliation. If he performs a forbidden act, expectations of punishment may result, guilt feelings may arise, and self-esteem and self-confidence may be diminished. In such a setting, anxiety no longer serves the adaptive function of instigating patterns of assertion that lead to mastery.

In the course of normal maturation, the child must also develop a confidence in his body, an understanding of bodily impulses, and a capacity for experiencing pleasure in them. The absence of these attitudes is expressed quite explicitly in childhood fears of being devoured—basic to which is the fear of being devourable by larger beings; it is implicit in the phobic adult's fears and feelings pertaining to dissolution of the body and his general immaturity about bodily relationships and functions.

As in other anxiety reactions, the phobic patient's past history has frequently unfolded in a setting in which communication about sex and aggression has been inhibited and in which repression has become a prominent defense. In our culture, which can be quite open in relation to hostile and sexual stimuli, it is difficult for massive repression to work indefinitely. When failures occur, other defenses, including displacement and avoidance, are then called into action.

In the adult who has the developmental history of the phobic personality, one frequently finds reports of multiple childhood fears: fear of the dark, of snakes, of swimming, of animals, or fear of being hurt. Such patterns are easily reactivated when difficult hurdles must be faced in later life. The child may simply copy or emulate a phobic, timid parent who communicates his attitudes to the child. Although not often reported in the initial histories taken of phobic patients, close investigation frequently reveals the presence of a phobic parent or other significant person in the life of the child who later becomes phobic. This may be repressed and not available to recall in the early stages of investigation.

Counterphobic defenses. Although superficially quite dissimilar from the pattern of avoidance utilized by most phobic patients, the reactive pattern of counterphobic behavior is nevertheless dynamically related. In such behavior, mastery of anxiety

is attempted through compulsive and repetitive confrontation with the source of anxiety in such a way that the person feels actively in control. The patient may feel driven to or attracted to the activity or object without consciously knowing why. Examination of such behavior reveals its *reactive* quality, basic to which is underlying fear and anxiety, which the person is unconsciously trying to master by his repetitive behavior. Implicit in this defense is the reasoning, "I'm really not afraid... see how brave I am!" This process is similar to that observed in children's play, children's dreams, and traumatic neuroses in which the person attempts to master his anxiety by repeating the situation that originally produced the threat.

The counterphobic behavior of parents of a phobic child became discernible in the course of investigation. The mother, originally so fearful of heights that she would not ride in elevators, mastered her fear by subsequently becoming an airlines hostess; following a serious heart attack and an accompanying depressive episode, the father compulsively engaged in athletic exercises more strenuous than any prior activity, in spite of warnings of his physicians.

Counterphobic behavior usually has a hollow quality that can be recognized by its exaggerated bravado, in a sense "above and beyond the call of duty." Because the real reasons for its perpetuation are usually not apparent to the patient, the pattern is an endlessly repetitive one.

Success phobia. The anxiety precipitated in some patients when they are placed in competitive situations, particularly ones involving vocational achievement and success, is frequently labeled "success phobia." Unconsciously fearing punishment for their own aggressive aspirations, these patients reveal a pattern of inhibition of aggression originally related to parental or sibling rivals. Although often dealt within the context of phobic reactions, success phobias, in the main, seem to represent what technically should be classified as anxiety reactions or some other disorder. A frequent paranoid integration has been noted by Ovesey, who also reported that these patients are often subject to the fear of blushing or to blushing itself.

Pathology

The phobic reaction is a disorder of psychogenic origin, without clearly defined physical cause or structural change occurring in the brain. Thus, it is not accompanied by pathological findings.

There is perhaps no psychic phenomenon more multidimensional in its origins or its expression than anxiety. Experimental evidence suggests that one's reactions to emotional emergencies or stress are related to dispositional tendencies that are determined by a combination of both psychological and biological factors. Experimental stress, for example, has been shown to elicit quite different cardiovascular responses in different individuals; these variations are

apparently related to genetic and innate biological factors and to the individual's early childhood experiences and his perception of the situation in which he finds himself at present. Many authorities infer that these extremely complex phenomena are instinctively rooted, varying from individual to individual.

Clinical Description

Fear. The outstanding characteristic of the phobic reaction is a persistent, excessive fear attached to an object or a situation that, objectively, is not a significant source of danger. Despite the fact that the phobic person's reality-testing ability is generally intact and although he usually regards his fear as inexplicable and irrational (even though he may offer rationalizations for it), he nevertheless experiences overpowering anxiety when confronted with the situation. He manifests such typical physiological reactions as excessive perspiration, tremor, pallor, tachycardia, rapid breathing, diarrhea, vomiting, and tightness in the chest. As a means of escaping such anxiety, the phobic person uses a pattern of avoidance in relation to the feared object or situation, thereby often greatly constricting his activity and functioning in daily life. Such avoidance at least makes the anxiety more manageable and life somewhat more tolerable.

Response pattern. A significant component in any manifest phobia is the response pattern that may be elicited by the feared object. In this sense, the phobia is purposeful, and, like other neurotic symptoms, involves secondary gains. Thus, a fear of snakes which may occur in a city dweller, does little to restrict his daily life. Likewise, a fear of subways would be inconsequential to an individual living in a rural community with no opportunity for riding the subway. For a person whose livelihood depends upon traveling to work by the subway, this fear might become charged with implications and meanings, having both obvious and subtle rewards as well as limitations. This fear would then constitute a phobia in the active, clinical sense. Cultural factors thus influence the type of phobia likely to occur in any setting.

To be classified technically as a phobia, the patient's response should include displacement and avoidance as defenses. Rather specific psychodynamics are posited for the phobic reaction. Fears of vague states or conditions such as fear of dying, or of the future, are common in anxiety reactions; repetitive but ego-alien ideas about dreaded acts are common in obsessive-compulsive reactions; fears of certain diseases are common in hypochondriacal reactions. Contrary to the designations sometimes given all these, they are properly labeled as phobias only when the response to them leads the patient to avoid some object or situation (such as heights, crossing of streets, hospitals) that becomes the focus or symbol of the fear. For example, in a postpartum depressive reaction, a mother's self-depreciation, lack of self-

confidence, and fear of responsibility may result in the fear that she may injure her child. Again, this would not technically constitute a phobia unless the fear was displaced to some object or entity such as knives, which was then avoided as a way of making life more comfortable.

Focus. Common objects or situations that may become the focus of a phobia include heights, closed spaces, subways, elevators, dirt, germs, open spaces, water, crowds, animals, and the dark. Phobias have traditionally been classified according to type by means of Greek prefixes, as indicated by the following examples:

acrophobia	fear of heights
agoraphobia	fear of open places
ailurophobia	fear of cats
cynophobia	fear of dogs
aquaphobia	fear of water
mysophobia	fear of dirt and germs
zoophobia	fear of animals
claustrophobia	fear of closed spaces
xenophobia	fear of strangers
pyrophobia	fear of fire

In recent years, such classification is not considered feasible since the theoretical possibility that any object or situation may become the focus of a phobia would result in the useless proliferation of labels. Furthermore, there is the disadvantage of stressing the differences in such irrational fears rather than the more important similarities in the past experiences and present personalities of individuals who become phobic. In addition, some patients develop numerous phobias, so that the object of the phobia often seems less consequential than the patterns of anxiety and avoidance that are specifically represented.

There are many objects and situations that most people dislike or fear to some extent, such as snakes, death, and heights. Freud gave recognition to this fact in his differentiation of phobias according to the nature of the feared object: common phobias, those representing an exaggeration of what are common and universal fears; contingent phobias, fears of special circumstances, specific to the individual. Many fears are common, and some can be rationalized as having a realistic basis. Although in theory it may seem difficult to differentiate a normal fear from a phobia, in actual practice the patient's response to the object usually indicates how rational his fear is, and to what degree both the fear and the reaction to it are appropriate or adaptive. Thus, to evaluate a fear of heights or a fear of cancer, one need not become involved in the statistics of airplane accidents or cigarette smoking. The phobic patient himself usually recognizes the irrational intensity and inappropriateness of his response to the situation. Sometimes the mere thought of the object precipitates an acute anxiety reaction.

Effect. Phobias may be extremely disabling. Some

phobic persons cannot leave their homes. They frequently cannot cross the threshold of a certain room. They feel helpless and are often unable to work or move about. Confrontation with the feared object may precipitate an acute panic reaction that is extremely painful.

Because the impairment in ability to function may be great, some authorities assume that a severe phobia must represent an underlying psychotic process rather than a psychoneurotic reaction, even when the primary signs of a psychosis are not discernible. Although this assumption has sometimes been proved accurate, at least part of the possible confusion arises from a nosological system that maintains distinctions without clear cut operational definitions, relying alternately on clinical signs, psychodynamic tenets, and inferred constructs and treatment responses. Thus, the degree of social incapacitation resulting from a phobia may be greater than that occurring with more formidable sounding symptoms, or it may be significantly less so.

Differential Diagnosis

Fears versus phobias. Theoretical discussions of phobias invariably indicate that there are many objects and situations people dislike or fear to some extent and that even normal individuals have mild phobias. Although it may, therefore, seem difficult to differentiate what is normal from what is psychoneurotic, in actual practice it is the patient himself who usually indicates clearly the degree to which his feelings and his responses to them are appropriate and rational. As is true of anxiety reactions in general, the patient, given the opportunity, usually communicates his distress in direct terms. Contrary to the designation sometimes given them, not every irrational fear necessarily represents a phobia in the strictest technical sense. Specific psychodynamics are posited for a phobia, including the defenses of displacement and avoidance.

Phobic reactions, anxiety reactions, and conversion reactions. As examples of neurotic disorders in which there is no gross distortion of external reality and in which the major defense is repression, these disorders have much in common. In anxiety reactions, however, the anxiety is experienced as diffuse and unspecified, not restricted to any definite situation or object. The primary defensive strategy is repression. In a phobic reaction, anxiety becomes attached to some specified object or situation, which then can be avoided. The anxiety thus becomes manageable in that the person is left with some control over his present state. The primary defensive strategies are repression, displacement, and avoidance. In conversion reaction, however, anxiety is converted into a functional symptom in organs or parts of the body that are mainly under voluntary control. A symbolic resolution of the conflict is obtained, often with prominent secondary gain. In all three, the physiologi-

cal manifestations of anxiety may be either reported or observed, and it is important to distinguish the somatic pattern that accompanies anxiety, involving the cardiovascular and gastrointestinal systems in particular, from that of specific organic pathology.

Phobia (symptom) versus phobic reaction (syndrome). Phobias occur in a variety of disorders. For example, they may represent extensions of what is basically an obsessive-compulsive reaction or a paranoid reaction. On the other hand, a phobia may also be one of many symptoms in a disorder that ultimately is revealed to be schizophrenia. In the pseudoneurotic type of schizophrenia in particular, neurotic-like symptoms (phobic, hysterical, and obsessive-compulsive) may occur in the context of panic-anxiety, masking the underlying schizophrenia. Some authorities feel that a severe phobia is usually an indication of an underlying psychotic state, even when the primary signs of a psychosis are not immediately revealed. Because of the variety of possibilities present, careful evaluation is necessary to make a proper diagnosis. Psychological tests, particularly the Rorschach test, are often helpful in this regard. To repeat, by present A.P.A. nomenclature, the term "phobic reaction" is reserved for those disorders in which the phobia is the major symptom and in which reality testing is intact. As an example of a disorder in which there is neither gross distortion of external reality nor evidence of structural or organic changes, the phobic reaction is thus classified under the heading of neurotic or psychoneurotic disorders.

Displacement (phobic) versus projection (paranoid). In the displacement that occurs in the phobic reaction and in the projection that occurs in paranoia, the world is distorted in terms of inner impulses and needs. The implicit assumption in each is, "It can't be me; it's out there." The degree to which responsibility can be transferred to outside causes can appear similar in individuals who utilize either displacement or projection. Unlike the paranoid individual, however, the phobic person retains better ability to test reality, recognizing that his feelings are irrational, in spite of the fact that he may at times offer rationalizations for them. He retains some possibility of action in that he has an available escape through avoidance, a defense he consciously recognizes. The paranoid patient, on the other hand, frequently feels himself passive or helpless in relation to his persecutors, accepting his delusional fears as appropriate to the threat which he feels exists.

Management

The techniques reported for the treatment of phobias and the phobic reaction represent the gamut of general therapeutic procedures, including psychoanalysis, deconditioning, hypnosis, client-centered therapy, reassurance, group therapy, environmental manipulation, and drugs.

Symptomatic treatment. The distinction between

stages rather than when removal of the phobia has been attempted precipitously with one suggestion.

Group therapy. Group therapy has also been successfully applied to the treatment of phobic reactions. Tentative research evidence suggests that the best results are obtained when desensitization procedures are combined with usual group methods.

Procedure. In general, a combination of some understanding of the psychodynamics of the particular situation combined with an understanding of the early fearful situations in childhood is usually most helpful in treating phobic individuals. The task is made easier if there has been a phobic parent whose pattern can be clearly distinguished from that of the patient. The companion to the patient can be very helpful to the therapist because he has extraordinary power over the patient and is endowed by the patient with attributes that border on magical. Although it is unwise to divorce the companion from the phobic patient abruptly, it is often possible to show the patient how he is using the other person in a destructive and hostile fashion. It is helpful if the patient can come to understand the psychodynamics of his early phobia and his wish to be taken care of. Since a great deal of secondary gain accrues to the phobic patient in terms of care, attention, and support, it is often necessary to reduce such rewards. This rational approach works with many phobic patients. It is probably best to reduce the magic in the situation to a minimum, letting the patient recognize that there is no miraculous cure, and that overprotection, love, and support will not allow him to master situations because such aid is necessarily contingent on other people.

Prognosis

Unfortunately, there are no adequately controlled statistical studies that show the relative effectiveness of varying therapies as contrasted with spontaneous remission rates. Evaluating the effectiveness of any therapy presents as yet unsolved problems of research related to the control of patient, therapist, and therapy, and criteria of improvement.

Opinion varies as to outcome, remission probabilities, chronicity, and therapeutic effectiveness in the treatment of phobias and phobic reactions. In general, a high degree of optimism can be reported, but some phobias are nevertheless found to be quite resistant to therapeutic endeavors. This seems to be particularly true when the phobia is superimposed on or is an extension of some disorder more regressive than that technically labeled "phobic reaction." In such instances, the management of the phobia itself may be the least difficult of the problems encountered.

Mild phobias can often be easily managed with supportive and directive techniques, including explanation, education, and reassurance. As with anxiety reac-

tions in general, symptomatic relief is frequently easy to obtain. The life-long dependency patterns of phobic patients, however, present problems that may necessitate intensive psychotherapy if underlying difficulties are to be resolved.

The efficacy of symptomatic treatment can be judged only in terms of the personality context in which the phobia occurs. Relevant issues include all components of ego strength, not the least of which are the patient's reality-testing ability and his ability to tolerate tension and postpone gratification. In many instances, symptomatic relief may be all that is indicated; in other instances, it is all that can be hoped for. Not unrelated to the choice of treatment goals is the patient's own perception of his difficulties and what he wants to do about them.

Suggested Cross References

For further discussion of the clinical manifestations and psychodynamics of anxiety see Lief's section on anxiety reaction (Section 23.1). Malmö describes the peripheral physical concomitants of anxiety and fear in Section 29.4, while an account of the central cerebral processes concerned with emotional arousal may be found in Sections 2.5 to 2.9, in Area B, on the basic behavioral sciences. That same area also contains a section by Bachrach on learning theory (Section 3.3). Further comments on the problems of nosology may be found in Brill's section (Section 14.1). More detailed information on phobias of childhood may be found in LaViertes' section (Section 43.6), which deals in part with school phobias, and in Anthony's section on childhood neuroses (Section 41.1). Finally, more detailed information regarding the treatment modalities mentioned in this section—namely, psychoanalysis and psychotherapy, behavioral therapy, group therapy, hypnosis, and drug therapy—may be found in Sections 34.1, 34.2, 34.6, 34.4, and 35.1, respectively, in Area G, on psychiatric treatment.

Chapter 24

Psychoneurotic Disorders. II: Obsessive-Compulsive and Neurotic Depressive Reactions

24.1 OBSESSIVE-COMPULSIVE REACTION

JOHN C. NEMIAH, M.D.

In one of his earliest psychological papers, Freud wrote:

If someone with a disposition [to neurosis] lacks the aptitude for conversion but if, nevertheless, in order to fend off an incompatible idea, he sets about separating it from its affect, then *that affect is obliged to remain in the psychical sphere*. The idea, now weakened, is still left in consciousness, separated from all association. *But its affect, which has become free, attaches itself to other ideas which are not in themselves incompatible; and thanks to this 'false connection,' those ideas turn into obsessional ideas*. This, in a few words, is the psychological theory of obsessions and phobias.

Freud's first psychodynamic formulations were created to account for the formation of the symptoms of conversion hysteria. When an idea is incompatible with an individual's ego (so ran his theory), the affect associated with the idea is rendered unconscious by repression and is converted into a sensorimotor disturbance that symbolically represents the unacceptable idea. The formulation was a satisfactory one, for it adequately explained the observed clinical manifestations of the conversion reaction: the existence of somatic sensory or motor symptoms, the absence of distressing affects associated with them, and the disappearance of the symptoms when the pathogenic idea and the associated painful affects were brought into the individual's conscious awareness by therapeutic techniques, such as hypnosis.

It soon became apparent, however, that the theory was not adequate to explain other forms of neurotic symptoms. In patients suffering from obsessions and phobias, for example, the predominant clinical mani-

festations were not somatic but psychic; instead of being disabled by disturbances in his sensations or motor functions, the patient was afflicted by distressing, consciously experienced ideas. Furthermore, in contrast to conversion symptoms, these ideas were accompanied by an acute, conscious awareness of painful emotions like anxiety or shame. In other words, at the very beginning of his attempt to develop a psychodynamic psychopathology, Freud was faced with the problem of explaining symptom choice and was forced to modify his theories to satisfy the demands of stubborn clinical facts—a process that continued throughout his long and creative career and led eventually to the highly elaborate web of contemporary psychoanalytic theory.

In this first expansion of his psychological formulations, Freud separated off from the somatosensory symptoms of hysteria a group of symptoms characterized by their psychical nature, but he failed initially to differentiate between phobic and obsessive-compulsive phenomena; this came later in his expanding psychodynamic scheme. There was, however, good reason for this early confusion. Not only do phobic and obsessive-compulsive symptoms have features in common, but the characteristics that are used to differentiate them clinically do not always lead to a clear separation. In fact, the clinical phenomena lie along a spectrum. Clearly differentiated at the extremes, there are forms in the middle of the spectrum in which it is difficult to decide to which category they should be assigned. Indeed, some contemporary authors still include phobias in the clinical syndrome of the obsessive-compulsive reaction.

Definition

Despite the existence of these areas of confusion, it is possible to designate certain symptoms as obsessions and compulsions and to distinguish them from other clinical manifestations by their specific charac-

teristics. Direct observation of the phenomena themselves provides the surest approach to a definition of these two symptoms.

In his autobiographical volume, *Lavengro*, that enchanting English vagabond George Borrow has reproduced a tale told him by a stranger he encountered in his wanderings.

Amid darkness and gloom, occasionally broken by flashes of lightning, the stranger related to me, as we sat at the table in the library, his truly touching history. . . .

'There was one thing that I loved better than the choicest gift which could be bestowed upon me, better than life itself—my mother; at length she became unwell, and the thought that I might possibly lose her now rushed into my mind for the first time; it was terrible, and caused me unspeakable misery, I may say horror. My mother became worse, and I was not allowed to enter her apartment, lest by my frantic exclamations of grief I might aggravate her disorder. I rested neither day nor night, but roamed about the house like one distracted. Suddenly I found myself doing that which even at the time struck me as being highly singular; I found myself touching particular objects that were near me, and to which my fingers seemed to be attracted by an irresistible impulse. It was now the table or the chair that I was compelled to touch; now the bell-rope; now the handle of the door; now I would touch the wall, and the next moment stooping down, I would place the point of my finger upon the floor: and so I continued to do day after day; frequently I would struggle to resist the impulse, but invariably in vain. I have even rushed away from the object, but I was sure to return, the impulse was too strong to be resisted: I quickly hurried back, compelled by the feeling within me to touch the object. Now, I need not tell you that what impelled me to these actions was the desire to prevent my mother's death; whenever I touched any particular object, it was with the view of baffling the evil chance, as you would call it—in this instance my mother's death.

'A favourable crisis appeared in my mother's complaint, and she recovered; this crisis took place about six o'clock in the morning; almost simultaneously with it there happened to myself a rather remarkable circumstance connected with the nervous feeling which was rioting in my system. I was lying in bed in a kind of uneasy doze, the only kind of rest which my anxiety, on account of my mother, permitted me at this time to take, when all at once I sprang up as if electrified, the mysterious impulse was upon me, and it urged me to go without delay, and climb a stately elm behind the house, and touch the topmost branch; otherwise—you know the rest—the evil chance would prevail. Accustomed for some time as I had been, under this impulse, to perform extravagant actions, I confess to you that the difficulty and peril of such a feat startled me; I reasoned against the feeling, and strove more strenuously than I had ever done before; I even made a solemn vow not to give way to temptation, but I believe that nothing less than chains, and those strong ones, could have restrained me. The demoniac influence, for I can call it nothing else, at length prevailed; it compelled me to rise, to dress myself, to descend the stairs, to unbolt the door, and to go forth; it drove me to the foot of the tree, and it compelled me to climb the trunk; this was a tremendous task, and I only accomplished it after repeated falls and trials. When I had got amongst the branches, I rested for a time, and then set about accomplishing the remainder of the ascent; this for some time was not so difficult, for I was now amongst the branches; as I approached the top, however, the difficulty became greater, and likewise the danger; but I was a light boy, and almost as nimble as a squirrel, and, moreover, the nervous feeling was within me, impelling me upward. It was only by means of a spring, however, that I was enabled to touch the top of the tree; I sprang, touched the top of the tree, and fell a distance of at least twenty feet, amongst the branches; had I fallen

to the bottom I must have been killed, but I fell into the middle of the tree, and presently found myself astride upon one of the boughs; scratched and bruised all over, I reached the ground, and regained my chamber unobserved; I flung myself on my bed quite exhausted; presently they came to tell me that my mother was better—they found me in the state which I have described, and in a fever besides. The favourable crisis must have occurred just about the time that I performed the magic touch; it certainly was a curious coincidence, yet I was not weak enough, even though a child, to suppose that I had baffled the evil chance by my daring feat.

'Indeed, all the time that I was performing these strange feats, I knew them to be highly absurd, yet the impulse to perform them was irresistible—a mysterious dread hanging over me till I had given way to it; even at that early period I frequently used to reason within myself as to what could be the cause of my propensity to touch, but of course I could come to no satisfactory conclusion respecting it; being heartily ashamed of the practice, I never spoke of it to any one, and was at all times highly solicitous that no one should observe my weakness.'

In these few paragraphs are to be observed the distinguishing characteristics of obsessive-compulsive phenomena, which, when they form the predominant manifestations of a patient's psychoneurotic illness, go to make up the obsessive-compulsive reaction. The word "obsessive" (or "obsession") refers to an idea or thought, as, in the passage just quoted, the narrator's idea of his mother's death. The word "compulsive" (or "compulsion") refers to an urge or impulse to action that, when put into operation, leads to a compulsive act. Compulsive acts predominate in the narrator's description of his trials—touching the floor, climbing the tree.

Obsessions and compulsions have certain features in common: (1) An idea or an impulse obtrudes itself insistently, persistently, and impellingly into the individual's conscious awareness. (2) A feeling of anxious dread accompanies the central manifestation and frequently leads the individual to take counter-measures against the initial idea or impulse. (3) The obsession or compulsion is ego-alien—that is, it is experienced as being foreign to and not a usual part of one's experience of oneself as a psychological being; it is undesired, unacceptable, and uncontrollable. (4) No matter how vivid and compelling the obsession or compulsion, the individual recognizes it as absurd and irrational—he retains his insight. (5) Finally, the person suffering from these manifestations feels a strong need to resist them.

Epidemiology

It is probably a rare person who has not at some time in his life experienced a fleeting bit of obsessional thinking or compulsive behavior. But a transient unreasonable compulsion to check a gas jet that one knows is closed or a momentary urge to shout out an oath during a solemn ceremony hardly constitutes an obsessive-compulsive reaction, which in its severest forms can be as disabling to the sufferer as the most crippling physical illness.

The exact incidence of the obsessive-compulsive

reaction is hard to determine. Scattered anecdotal evidence indicates that it has occurred throughout history. Those who have studied the natural history of the disorder have found an incidence that is never higher than 5 per cent of all psychoneurotic patients, the percentage, of course, being lower if the total population includes patients with psychoses.

It is possible that the figures given are lower than the actual incidence of the obsessive-compulsive reaction in the community at large. The figures have been derived from those patients who have actually come to the psychiatrist's attention in either an in-patient or an out-patient facility. It is known that individuals with obsessive-compulsive disorders tend to be secretive about their symptoms and to avoid disclosing them to physicians, often doing so only when some other illness has forced them to seek medical attention. Furthermore, since people with obsessive-compulsive symptoms are frequently able to work and earn a living despite marked limitations in their social and emotional life, their disorder may never be known except to their closest associates. Facts such as these suggest that the incidence based on figures derived from clinical populations is spuriously low.

There appears to be no significant sexual difference in the disorder, and the larger the series of patients, the more the percentage of men and women afflicted is equal. It is interesting that a large proportion of obsessive-compulsive patients remain unmarried, up to 50 per cent in some surveys. Recent studies indicate that the frequency of the disorder is higher in upper class individuals and in those with higher intelligence levels.

Clinical Description

Because of the relative rarity of the disorder and of the paucity of patients adequately studied, it is difficult to make categorical statements about the natural history of this psychoneurotic reaction. All that is said in the following pages about the course, prognosis, and etiology must be considered as only tentative and perhaps applicable only to selected patients rather than to the syndrome itself.

Onset. The onset of the disorder occurs predominantly in adolescence or early adulthood. The symptoms first appear in over two thirds of the patients by the time they are 25 and frequently before the age of 10. In less than 5 per cent do the symptoms begin for the first time after the 4th decade of life. As compared with patients suffering from conversion symptoms or anxiety, those with obsessions and compulsions seek professional help at an earlier age. In one series of patients, the average age when they first saw a doctor was 22.0 years for the obsessive-compulsive group, 30.3 for the hysterical patients, and 32.2 for those with anxiety. In over half the patients a clear environmental precipitating event can be found. For example, immediately following a hemorrhoidectomy, a man developed the obsession that he was going

to harm others by inadvertently knocking them down or contaminating their food with dirt. A woman in her thirties was driven home in her own car one evening by a male acquaintance. On the way, her companion stopped by the roadside to void in the bushes. Later that night she had the sudden thought that urine from his hands might have dirtied the steering wheel. Then and there she spent an hour scouring out the inside of her car with soap and water, and afterward she scrubbed herself vigorously in the bathtub. From that time on she was consumed by a washing compulsion that eventually led to her hospitalization.

Symptoms. The fundamental characteristics of obsessive-compulsive phenomena described earlier have a general validity and usefulness in distinguishing them from the manifestations of other emotional disorders. In attempting, however, to categorize the various obsessive-compulsive manifestations themselves, one is faced with a more complicated task, for the multiplicity of variables makes it difficult to devise a classification that will sharply differentiate one kind of obsessional or compulsive symptom from another.

The phenomena may be manifested psychically or behaviorally; they may be experienced as ideas or as impulses; they may refer to events anticipated in the future or actions already completed; they may express desires and wishes or protective measures against such desires; they may be simple, uncomplicated acts and ideas or elaborate, ritualized patterns of thinking and behavior; their meaning may be obvious to the most unsophisticated observer, or they may be the end result of highly complicated psychological condensations and distortions that yield their secret only to the skilled investigator.

No single classificatory scheme can do justice to clinical events that are compounded of these many features in almost endless variation, and the organization that is suggested in what follows is only one possible way of looking at the phenomena. In most general terms the symptoms may be divided into those that are psychic in nature and those that are manifested in observable behavior.

Psychic manifestations

Obsessional thoughts. Perhaps the simplest of the psychic symptoms are those in which thoughts, words, or mental images are obtruded against his will into the conscious awareness of the patient. In *Grace Abounding to the Chief of Sinners*, John Bunyan has left us his spiritual autobiography and a magnificent case history as well, for he has vividly described in these pages the variety of psychiatric symptoms from which he suffered, among them a paradigm of the obsessional thought.

The Tempter came upon me again, and that with a more grievous and dreadful Temptation than before.

And that was, *To sell and part with this most blessed Christ, to exchange him for the things of this life, for any-*

thing. The Temptation lay upon me for the space of a year, and did follow me so continually that I was not rid of it one day in a month, no, not sometimes one hour in many days together, unless when I was asleep. . . .

But it was neither my dislike of the thought, nor yet any desire and endeavour to resist it that in the least did shake or abate the continuation, or force and strength thereof; for it did always, in almost whatever I thought, intermix itself therewith in such sort that I could neither eat my food, stoop for a pin, chop a stick, or cast mine eye to look on this or that, but still the temptation would come, *Sell Christ for this, or sell Christ for that; sell him, sell him.*

Sometimes it would run in my thoughts, not so little as a hundred times together, *Sell him, sell him, sell him;* against which I may say, for whole hours together, I have been forced to stand as continually leaning and forcing my spirit against it, lest haply, before I were aware, some wicked thought might arise in my heart that might consent thereto. . . .

Bunyan's preoccupations and his language are, of course, partly determined by his 17th century surroundings, but the modern sinner has temptations to match his. Freud's famous Wolfman found himself from time to time compelled to think, "God-Shit" or "God-Swine." A young woman of 23 was shocked one day when the mental image flashed into her mind of her father and herself undressing one another and joining in a sexual embrace. From that time on, despite her desperate efforts to erase the image, it recurred with mounting intensity, and she finally fled to the hospital for help. A mother in her late thirties was tortured every time her daughter left the house by images of the child's being hit by a car. Particularly vivid was the mental picture of the little girl's body lying broken and bleeding in the gutter, and nothing she could do would exorcise the tormenting scene. A young law student had the frightening thought every time he turned on a light, "My father will die"; to allay his anxiety, he would have to touch the switch and think to himself, "I take back that thought."

In all these examples the obsessional thought refers to present or future time. In a minor variation of the theme the patient is preoccupied with a guilty dread that an action he has performed in the past has or will lead to dreadful consequences. A young man was constantly plagued every time he left his house with the fear that he had left a cigarette burning that would set the house on fire. An adolescent boy was tormented by the thought after he had masturbated that his semen had been spread about and would impregnate his mother and sisters. For days after she had kissed a boy, a young woman was obsessed with the idea that she was pregnant. A married accountant of 37 could not shake the idea from his mind that he had accidentally bumped passersby on the street or in the subway and that, as a consequence, they had fallen and been severely injured or killed.

A special form of forced preoccupation with thoughts is designated by the term "obsessive-ruminative states." As the term implies, the central feature is rumination about a topic or problem, often of a re-

ligious or abstrusely philosophical nature. The pros and cons of the questions are repetitively considered, and imponderables are weighed in a prolonged, fruitless, and inconclusive inner dialogue, filled with doubting and despair. Bunyan was an adept at such interior debate. He tells us how

...blasphemous thoughts...stirred up questions in me, against the very *Being* of God, and of his only beloved Son; as, whether there were, in truth, a God, or Christ? And whether the holy Scriptures were not rather a Fable, and cunning story, than the holy and pure Word of God?

The Tempter also would much assault me with this, *How can you tell but that the Turks had as good Scriptures to prove their Mahomet the Saviour, as we have to prove our Jesus is? And, could I think, that so many ten thousands, in so many Countries and Kingdoms, should be without the knowledge of the right way to Heaven, (if there were indeed a heaven), and that we only, who live in a corner of the Earth, should alone be blessed therewith? Every one doth think his own religion rightest, both Jews and Moors and Pagans! and how if all our Faith, and Christ, and Scriptures, should be but a Think-so too?*

Sometimes I have endeavoured to argue against these Suggestions, and to set some of the Sentences of blessed Paul against them; but, alas! I quickly felt, when I thus did, such arguings as these would return again upon me, *Though we made so great a matter of Paul and of his words, yet how could I tell but that in very deed, he being a subtle and cunning man, might give himself up to deceive with strong delusions; and also take the pains and travel to undo and destroy his fellows?*

These suggestions, (with many others which at this time I may not, nor dare not utter, neither by word nor pen,) did make such a seizure upon my spirit, and did so overweigh my heart, both with their number, continuance, and fiery force, that I felt as if there were nothing else but these from morning to night within me; and as though, indeed, there could be room for nothing else. . . .

Compulsions. In another form of the psychic phenomena, ideas and images may be present, but the central feature is an irrational impulse to some form of action. The impulse, however, remains merely an impulse and is not acted on by the patient, no matter how fearful he may be that he will lose control of his behavior. As earlier defined, this clinical manifestation is known as a *compulsion*. In yet another passage from his richly clinical autobiography, Bunyan exemplifies this symptom:

One day as I was betwixt *Elstow* and *Bedford*, the temptation was hot upon me, to try if I had Faith, by doing of some Miracle: which Miracle at that time was this, I must say to the *Puddles* that were in the horse-pads, *Be dry; and to the dry places, Be you the Puddles.* And truly, one time I was going to say so indeed; but just as I was about to speak, this thought came into my mind, *But go under yonder Hedge and pray first, that God would make you able.* But when I had concluded to pray, this came hot upon me, That if I prayed, and came again and tried to do it, and yet did nothing not withstanding, then be sure I had no Faith, but was a Cast-away and lost. Nay, thought I, if it be so, I will never try yet, but will stay a little longer.

So I continued at a great loss; for I thought, if they only had Faith, which could do so wonderful things, then I concluded that, for the present, I neither had it, nor yet, for time to come, were ever like to have it. Thus I was tossed betwixt the Devil

and my own Ignorance, and so perplexed, especially at some times, that I could not tell what to do.

The modern day patient is perhaps more prosaic and less articulate than his Puritan predecessor, but he has, nonetheless, quite similar symptoms. He may feel the impulse to jump out of the window of a high building or to throw himself in the path of a moving train or car. His aggressions may be aimed at others rather than himself. A man constantly had the urge to push people down elevator shafts and avoided elevators lest his temptations be too strong. A young mother was beset with the impulse to beat her infant baby when he cried and at times had the urge to pick him up by the heels and bash his head against the wall. Others are driven by impulses to stab those around them with knives, scissors, or other sharp objects. The aggressive compulsion need not be physical but may be an urge toward an act of defiance or one that is socially inappropriate or shocking, such as shouting obscenities in church. Although these impulses do not lead to action, they frequently arouse strong anxiety in the patient and cause him to avoid the situation or object that evokes the impulse. Such an avoidance reaction is shared by individuals with compulsions of this sort and by those with typical phobic reactions.

Behavioral manifestations. When the obsessive-compulsive phenomena are psychic, no one would know that there was anything unusual going on in the patient unless he chose to divulge his purely private experiences. The situation is obviously quite different in the case of compulsive acts, where the phenomena are behavioral and usually visible to anyone who is there to see them, although often out of shame or embarrassment the patient will try to restrict his actions to those times when he is alone. There are two principle types of compulsive acts: (1) those that give expression to the primary urges or impulses that underlie them and (2) those that are a reaction to or an attempt to control the primary impulse.

Compulsive acts that simply and directly express the underlying urges are rare, although they do occur, as in the case of a young single woman who felt compelled to keep her diaphragm on top of her Bible in her bureau drawer, and did so. In most instances the compulsion expressing an urge remains in the psychic sphere and is not visible in action, except when it contaminates a compulsive act that began as a controlling maneuver.

In general, compulsive acts are, or at least begin as, attempts to control or modify a primary obsession or compulsion, either because the patient fears the consequences of his obsession, or because he is afraid that he will not be able to control his impulse. Such defensive compulsive acts are employed to contain, neutralize, or ward off the feared results of concurrent obsessions and compulsions, or they

may represent a desire to make sure that some action in the past has not led to disaster.

Compulsive acts of the first type were particularly prominent in Borrow's account of the young tree climber, whose actions were all aimed at preventing his mother's death, which he obsessively feared. The same motivation was apparent in the law student who had to touch the light switch after turning it on to counteract his thought that his father might die.

Bunyan tells us that in attempting to resist the evil thought to sell Christ

...by the very force of my mind, in labouring to gainsay and resist this wickedness, my very body also would be put into action or motion by way of pushing or thrusting with my hands or elbows, still answering as fast as the destroyer said, *Sell him; I will not, I will not, I will not, I will not; no, not for thousands, thousands, thousands of Worlds.* Thus reckoning lest I should, in the midst of these assaults, set too low a value of him, even until I scarce knew where I was, or how to be composed again.

A man in his thirties, fearing lest he push a stranger off the subway platform in the path of an oncoming train, was compelled to keep his arms and hands glued rigidly to his sides. The same patient, obsessed with the idea that dirt from his hands might harmfully contaminate others, often spent hours compulsively washing himself. The elaborate, ritualized preparations that some patients are compelled to carry out on going to bed may be a conscious attempt to control an impulse to masturbate.

Certain compulsive acts, as has been mentioned, are motivated by a guilty dread on the part of the patient that he has done something bad and are designed to atone for his sins or to reassure him that things are, in reality, all right. The patient who kept his arms tight against his sides was on one occasion obsessed with the idea that, despite his stringent precautions, he had, after all, inadvertently knocked someone off the subway platform. He struggled with himself for weeks to dispel what he rationally knew was a foolish notion but was at length compelled to call the transport authority to reassure himself that there had not in fact been any such accident. The same patient was for a time preoccupied with the concern that, when he walked on the streets, he was dislodging manhole covers so that strangers passing by would fall into the sewer and be injured. Whenever he passed a manhole in the company of friends, he would be compelled to count his companions to make sure that none was missing. Another patient who was beset by the same fear, that by accidentally bumping strangers he had caused them to fall and be injured, felt compelled to return to the scene of his supposed wrongdoing to determine whether anything really had happened. He would not rest easy until he was certain that no harm had been done.

The purpose of these compulsive acts was evident to the patient or the observer or both. There are, however, compulsive phenomena the meaning of

which is obscure and can be ascertained, if at all, only by a painstaking exploration of the patient's psychic function and associations. Two commonly found compulsive symptoms often fall into this category: the compulsion to touch (as seen in Borrow's acquaintance) and the compulsion to count. A patient is frequently compelled to utter an idiosyncratic, cryptic, seemingly nonsensical word that on careful examination proves to be a highly condensed and abbreviated formula, the function of which is to ward off or neutralize an underlying impulse. Such was the nonsense word "Glejisamen" uttered by Freud's Ratman. On analysis the word proved to be composed of the initials of the first words of several short protective prayers prefixed to "Amen."

Those compulsive acts that have already been examined have been relatively simple, straightforward, usually meaningful single actions. At times, however, the patient's compulsive behavior may become highly elaborate and repetitively stereotyped in the form of compulsive rituals. On going to bed, for example, the process of taking off one's clothes must conform to an exact pattern; they must be placed exactly so on a chair or hanger; the sequence of washing, voiding, and brushing one's teeth is rigidly adhered to; the furniture in the bedroom, the bedclothes, and pillow must be symmetrically arranged. Any deviation in the pattern arouses anxiety in the patient, and he must be certain that all has been done properly before he can drop off to sleep. Often the same process must be carried out in reverse when he gets up in the morning and prepares for the day.

A man of 32 who worked on the assembly line of an electronic concern developed the following compelling ritual: before he could solder one piece to another, he had to tap the work bench three times with his left hand and three times with his right, followed by stamping three times on the floor with his left foot, then with his right. For a time this merely slowed down his work performance, and he was able to continue his job. Gradually, however, an element of doubt crept into his mind. After completing a sequence of tapping and stamping, doubting thoughts would flash into his consciousness: "Did I really do it right? Am I sure that I tapped three times? Did I stamp with my left foot first?" In response to these questions, he had to repeat the ritual to make sure it was perfectly done; but, the more he performed it, the greater his doubt. Before long, almost his entire working day was taken up by his rituals, and he was forced to leave his job.

The element of doubt manifested by this last patient has been evident in some of the clinical examples already examined, especially in Bunyan's confessions and in the phenomenon of obsessional rumination. It is, indeed, often found in connection with compulsive acts performed to ward off the feared consequences of obsessional ideas and compulsive urges. These fail to be dissipated or quieted by the compul-

sive acts employed against them, and the patient is never sure that he has contained his ever pressing impulses, that they have not somehow leaked out inadvertently into his behavior or in some other way created the trouble he is at such pains to avoid. And often the patient's concerns are justified. Despite the best of his cautious intentions, the underlying impulse may manifest itself in the very process of carrying out defensive compulsive acts and may distort these actions so that they achieve or at least seem to the patient to achieve exactly the effect they are designed to prevent. One of Freud's patients, for example, spent hours saying simple prayers designed to combat obsessional ideas of harm coming to others, but when he wished to say, "May God protect him," he would find the words coming out, "May God *not* protect him."

A woman in her late thirties was obsessed with the idea that her excreta might offend or harm other people. During a stay on a psychiatric ward she spent long periods of time washing in the communal bathroom after voiding or defecating. She would throw her skirts and petticoats over her head and scrub the entire lower part of her body, especially her genitalia and anus. Then the toilet seat and walls of the toilet stall would be scoured with soapy water. Finally, her hands would be mercilessly scrubbed, often to the point where they were red and raw. When she finished her ablutions, she and the toilet were spotlessly clean, but the rest of the bathroom was a shambles—dirty, soapy water still filling the wash basins, the floor awash with sudsy water, and countless soggy paper towels thrown about with complete abandon, littering the fixtures and floor. In the end, the other patients on the ward were infuriated by the amount of time the patient spent in the bathroom and by the filthy mess she created by the very process that was designed to control her dirtiness and to protect the other people around her.

Character traits. Much has been written about the nature of obsessive-compulsive character traits, and the person who exhibits them has been described variously in the literature as having an obsessional character, an anal personality, or an anancastic personality. All these terms refer to a group of behavioral phenomena characterized by control, in contrast to the hysterical personality, where a tendency toward a flamboyant expression of fantasies and feelings predominates.

As he is observed and experienced by others, the individual with obsessional personality traits is seen to exercise a marked measure of control over both himself and his environment. He is cautious, deliberate, thoughtful, and rational in his approach to life and its problems and may appear dry and pedantic when these traits are carried to an extreme. He emphasizes reason and logic at the expense of feeling and intuition, and he does his best to be objective and to avoid being carried away by subjective

enthusiasms. As a result, he often appears sober and emotionally distant, but at the same time he is found to be a person with great steadiness of purpose, reliability, and earnest conscientiousness. What he lacks in flexibility, imagination, and inventiveness, he makes up for in a conservative cautiousness about change that provides a salutary balance to the transient but violent enthusiasms of others.

In addition to his need to restrain himself and his emotions, he likes to feel that he has control of his environment as well. He subscribes to the dictum, "A place for everything, and everything in its place," and neatness, orderliness, and tidiness characterize his arrangement of space, as does punctuality his management of time. He likes people and institutions that behave predictably and conform to his predilections. He can be surprisingly obstinate and stubborn when challenged or contradicted. He sets great store by justice and honesty, has a strong sense of property rights, manages his own resources with frugality, and does not easily part with his possessions.

It needs to be emphasized that the presence of obsessional character traits is not in itself an indication of abnormality. On the contrary, they may be a great asset to their owners, and society owes much of its stability and its efficiency to its more obsessional members. It is only when such traits are carried to an extreme or when the balance between control and impulse expression leads to paralysis that they become a liability. Furthermore, there is no necessary connection between obsessional character traits and obsessive-compulsive symptoms. The incidence of the obsessional personality in the population at large is not known with any accuracy, but it is far more common than the obsessive-compulsive reaction, which is relatively infrequent. Most people with obsessional character traits do not develop an obsessive-compulsive reaction, and the latter does *not* always arise from the soil of the obsessional personality. Indeed, in some 20 to 30 per cent of patients with obsessive-compulsive reactions, there is no history of prior obsessional character traits.

Mental status. The most obvious disturbances in behavior in patients with obsessive-compulsive reactions occur in those whose illness is characterized by compulsive acts. The elaborate rituals or stereotyped movements, if they are performed in the public eye, cannot be missed by the observer. Moreover, if the patient will divulge the nature of his inner obsessional thoughts and compulsive urges, these are often seen to be irrational and bizarre. At the same time it can be observed that the patient retains full insight: he recognizes that his pathological thoughts and impulses are quite unreasonable and alien to the mainstream of his personality. Apart from these obviously abnormal phenomena, there is little else that on casual examination will appear to be unusual. As one observes more closely and perceptively, however, one becomes aware of behavioral elements, most of which

are related to obsessive-compulsive character traits, although they are not invariably present in the obsessive-compulsive patient.

The patient is often neatly dressed and groomed, sometimes with almost fussy tidiness. Reserved and formal in manner, he sits before the examiner stiff and prim, showing little in the way of gestures or facial expression, and his movements are careful and precise without spontaneity or easy grace. The controlled quality of his posture and movement is matched in his speech. His sentences may be long and involved and full of stilted phraseology or stereotyped expressions. He characteristically balances one clause against another—"Whereas . . . , yet . . ."; "On the one hand . . . , on the other" He says the same thing several times in succession, introducing each paraphrase with "Again" or "In other words" or "To put it in another way." He qualifies any direct statement with words like "maybe," "perhaps," or "possibly," to avoid sounding dogmatic or to escape being caught in an error. He relies heavily on rational argument and talks in highly intellectual and intellectualized terms about the simplest matters, interlarding his pronouncements with the copious and needless interjection of words or phrases like "indeed," "to be sure," "be that as it may." He recounts events in infinite detail, with a painful attention to accuracy and completeness, sometimes referring to written notes he has brought with him. Often it turns out that he has rehearsed what he plans to say in the interview for hours before it takes place and has tried to anticipate every move and question the interviewer may introduce. Any attempt to hurry him along, to cut him short, to switch to another topic is met by the patient's resistance and rigid adherence to his preconceived program of action. Evidence or expression of emotion, save possibly controlled anxiety, is at a minimum or entirely absent. If he is sophisticated about psychiatric theory, and such patients often are, he will discourse at length about his "conflicts," his "defenses," his "aggression," or his "libido." But in answer to direct questioning, he will deny having any of the feelings related to these words. His self-awareness and self-knowledge, however extensive, are entirely intellectual in nature and quite without emotional correlates.

These patterns of behavior are apparent from the start, and they tend to be maintained intact by the patient over many hours of contact with his doctor. Despite the latter's attempts to focus on and to promote the expression of emotion, the patient maintains his formality and his distance, and a meaningful, warm, affective relationship appears to develop very slowly, if it develops at all. And yet the appearances can be deceptive, for in many patients evidence of a strong dependence on the doctor can be found early in the relationship, despite their attempts to control their emotions. The patient will ask anxiously for reassurance that his obsessional impulses

have not got out of control; he will be loathe to stop at the close of the interview, and the interviewer may have to cut him short; after leaving the office, he may come back a moment later to add a piece of information he had forgotten to mention. If the doctor casually passes the patient on the hospital wards, the patient, like iron to a magnet, is irresistibly drawn to approach the doctor to ask him a question or to make a comment, following him closely as he walks along, unable to let go until the doctor almost literally has to shake him off. The adjective "sticky" applied to such patients is entirely apropos.

Course and Prognosis

Accurate statements about the course and prognosis of the obsessive-compulsive reaction are precluded by the lack of detailed knowledge of the natural history of the syndrome. The number of series in which longitudinal studies have been carried out is small, and the figures now to be presented must be considered as first approximations at best.

On first consulting a physician for their difficulty, two thirds of the patients give a history of prior episodes of obsessive-compulsive symptoms, some 10 to 15 per cent having first experienced them before the age of 10. The large majority of patients have had only one such prior attack, although a good number (roughly 30 per cent) have experienced two or three episodes. In 85 per cent of these attacks the duration was less than a year, although some attacks may have lasted 4 to 5 years.

The figures given for the prognosis vary widely from series to series, but the following general statement may be made for patients followed up for anywhere from 1 to 10 years after treatment, excluding leukotomy: some 15 per cent are well, 45 per cent are improved, and 40 per cent are unchanged or worse. Those considered improved fall into two groups: (1) patients whose symptoms have lessened to a point where they are able to work and function socially, (2) those who run a fluctuating course, often with long periods of complete remission of symptoms.

In general, it may be said that the obsessive-compulsive reaction is a chronic disorder, often following a remitting course. The prognosis is better (1) the shorter the duration of symptoms prior to the time the patient is first seen, (2) the greater the element of environmental stress associated with the onset of the disorder, (3) the better the environment to which the patient must return after treatment, and (4) the better his general social adjustment and relationships.

Pathology

There is little that can be said conclusively about pathological processes in the central nervous system associated with obsessive-compulsive phenomena. Shortly after World War I, there was considerable interest in the possibility that brain lesions might be

related to obsessive-compulsive symptoms. It was noted that some patients following Economo's disease developed behavioral disorders that often appeared to be compulsive in nature. However, these phenomena differed from those seen in the classical obsessive-compulsive reaction in that they were primarily motoric and characteristically consisted of uncomplicated, stereotyped movements without associated mental content. Furthermore, much of the disturbed behavior that has followed encephalitis in more recent times has been characterized by impulsive, immature, antisocial actions that result from a loss of control of the impulse life—quite the opposite, in other words, from the excess of inner controls that is characteristic of individuals with obsessive-compulsive reactions.

In a small series of patients, Schilder found that two thirds of them showed neurological signs pointing to basal ganglia disease, but his prediction that the careful examination of patients with obsessions and compulsions would reveal such signs in a large number of cases has not been substantiated by subsequent investigators, nor did he have pathological material to complement his clinical findings. More recently, sporadic cases have been reported in which temporal lobe lesions are associated with obsessive-compulsive phenomena. Although studies such as these are interesting and suggestive, in the vast majority of patients with obsessions and compulsions, there is no observable evidence pointing to lesions in the brain. At present the most useful and most sophisticated explanatory concepts are the psychological theories of etiology.

Etiology

History

Early theories. In the *Malleus Maleficarum*, Heinrich Kramer and James Sprenger wrote of a 15th century patient whom one of them observed:

A certain Bohemian from the town of Dachow brought his only son, a secular priest, to Rome to be delivered, because he was possessed. It happened that I, one of us Inquisitors, went into a refectory, and that priest and his father came and sat down at the same table with me. We saluted each other, and talked together, as is customary; and the father kept sighing and praying Almighty God that his journey might prove to have been successful. I felt great pity for him, and began to ask what was the reason of his journey and of his sorrow. Then he, in the hearing of his son who was sitting next to me at the table, answered: 'Alas! I have a son possessed by a devil, and with great trouble and expense I have brought him here to be delivered.' And when I asked where the son was, he showed me him sitting by my side. I was a little frightened, and looked at him closely; and because he took his food with such modesty, and answered piously to all questions, I began to doubt that he was possessed, but that some infirmity had happened to him. Then the son himself told what had happened, showing how and for how long he had been possessed. . . . When I asked him about the length of the intervals during which he had the use of his reason more than is usual in the case of persons possessed, he answered: 'I am only deprived of the

use of my reason when I wish to contemplate holy things or to visit sacred places.'... When he passed any church, and genuflected in honour of the Glorious Virgin, the devil made him thrust his tongue far out of his mouth; and when he was asked whether he could not restrain himself from doing this, he answered: 'I cannot help myself at all, for so he uses all my limbs and organs, my neck, my tongue, and my lungs, whenever he pleases, causing me to speak or to cry out; and I hear the words as if they were spoken by myself, but I am altogether unable to restrain them; and when I try to engage in prayer he attacks me more violently, thrusting out my tongue.'

For 20th century minds, the concepts of witchcraft, of devils, and of possession that fill the *Malleus Maleficarum*—of the whole paraphernalia of external, independent immaterial beings in a spiritual world—are nothing but worthless superstition and delusion. It must be remembered, however, that for men of earlier ages these were real and useful ideas. They provided an explanation for the observed phenomena and constituted a seriously conceived theory based on observable facts. As the 17th century preacher Joseph Glanvil wrote in the introduction to his *Sadducismus Triumphatus*, a volume devoted to the proof of the existence of witches:

Whether Witches are, or are not is a Question of Facts: For it is in Effect, whether any Men or Women have been, or are in Covenant with evil Spirits, and whether they, by the Spirit's Help, or he on their Account, performs such or such things.... Matters of Fact can only be proved by the immediate Sense, or the Testimony of others, Divine or Human. To endeavour to demonstrate Fact, by abstract Reasoning and Speculation, is as if a Man should prove, that Julius Caesar founded the Empire of Rome, by Algebra or Metaphysics.

It is evident that Glanvil eschews logic chopping and deductive ratiocination. For him, the existence of witches is to be determined by observation. Although the modern scientist would not subscribe to Glanvil's reliance on divine testimony, he can find himself quite at home in the strictly empirical approach that Glanvil takes to his subject matter.

By the 19th century, of course, the climate of opinion had radically changed. Scientific theories no longer invoked sentient, purposeful spiritual beings as causal factors but relied on explanations that involved impersonal, measurable natural forces acting mechanically on material objects. This change is reflected in the language used by George Borrow in the case history quoted earlier. Although he does make passing reference to a "demoniac influence," Borrow's vocabulary is otherwise quite different. He speaks of "thoughts," "feelings," "impulses," "anxiety," "nervous feelings rioting within," "a mysterious dread." There is no talk of devils, witches, or possession by spiritual beings. His concern is only with mental events—thoughts, feelings, and impulses—that are contained within the confines of the individual's mind and body. The explanation of the phenomena has been shifted from external supernatural forces to a consideration of the inner workings of the human mind. Demonology has been replaced by psychology—a natural science.

Borrow was, of course, a layman, but the psychologists who were his contemporaries as well as those who followed him in succeeding decades were working within the same scientific frame of reference in their attempts to understand and explain the wide spectrum of normal and abnormal mental phenomena. Obsessions and compulsions had a significant place among the concerns of the clinicians. Two different and rival explanations were offered concerning these symptoms: (1) The primary disturbance lay in a not clearly specified defect in intellectual functions, leading to difficulties in making logical decisions and to an exaggerated preoccupation with certain ideas out of proportion to their importance. (2) The basic problem was a disturbance in the function of the emotions, especially anxiety, which, escaping control and becoming attached to an idea, forced it with undue intensity and persistence onto the patient's conscious attention.

Janet's theories. In 1903 was published Pierre Janet's two-volume work, *Obsessions and Psychasthenia*. From a wide range of clinical observations, Janet deduced a theoretical scheme that included many of the ideas of his predecessors and introduced certain concepts he considered basic to an understanding of the facts. For Janet the central disturbance lay in a pathological diminution of mental energy. As a consequence, there resulted a disintegration of the normal organization of mental functions, leading to a failure of the highest of these functions—those of will and attention, which enabled the individual to control his thoughts and actions, to perceive himself and his environment *realistically*, and to perform actions appropriate to that correctly perceived reality. When these higher mental functions were impaired or destroyed, lower, subsidiary, more primitive mental functions—essentially the emotions with their mental, visceral, and motoric correlates—escaped from control. Without regard for reality, they made their appearance in a chaos of mental anarchy. The lower functions operated with energy that was normally and naturally theirs and with an additional quantum of energy derived from the higher functions that were no longer operable once the whole psychic apparatus had fallen apart.

With this theoretical model, Janet attempted to provide a systematic explanation of a variety of clinical symptoms that he felt were related—the subjective sense of mental fatigue and depression (psychasthenia), obsessions, compulsive urges and acts, phobias, and anxiety attacks. Certain concepts contained in Janet's earlier theories concerning hysteria are to be found in this formulation, in particular the notion, basically a physiological one, that a diminution in energy leads to a disorganization of integrated personality structure, with a resulting autonomous, uncontrolled functioning of subsidiary mental functions. What is interesting is that the idea of

unconscious mental functioning, which had a place in Janet's explanation of hysteria, plays no part in this later theoretical scheme. The entire theoretical model hinges on a quantitatively and mechanistically conceived lowering of mental energy. Although attempts were made to account for this diminution as a result of emotional shock, physical illness, or hereditary degeneracy, its genesis was not satisfactorily explained.

By ignoring the concept of unconscious mental processes, Janet and those who preceded him compromised their capacity to illuminate the genesis of obsessive-compulsive phenomena. In some ways the earlier demonological theories provided a more complete and a more dynamic explanation of the symptoms than the more naturalistic hypothesis of the 19th century. The earlier observers, confronted with the directly observable central feature of the obsession or compulsion as an insistent idea or urge imposed on an individual by some force seemingly outside himself, took these observations at face value. The compelling force that was *experienced* as external was, they argued, *in reality* external in the form of the devil or some related spiritual being. (The Ptolemaic cosmology took the same literal approach to physical phenomena: Since the sun and stars were observed to revolve around the earth, it was assumed that they did in fact do so.) The scientific climate of opinion in the 19th century forbade belief in demons, but the facts persisted.

Psychoanalytic theories. It remained for Freud, by exploiting the possibilities offered by the concepts of the unconscious and of psychological conflict, to devise a theory of the obsessive-compulsive reaction that would explain it in terms of its psychogenetic roots in the early phases of childhood development and of the psychodynamic factors important in the production of its symptoms. His point of departure lay in his early recognition that the difference between hysterical and obsessional symptoms rested on a difference in the psychological mechanisms that led to their formation. Although his earliest formulation was in many ways incomplete, it provided a beginning from which he and his co-workers gradually evolved the theoretical explanation that is widely accepted today. In what follows the current theory will be discussed with respect to (1) psychodynamic factors, (2) psychogenetic roots, and (3) the central role of regression in the production of the disorder.

Psychodynamic factors. There are three major psychological defensive mechanisms that determine the form and quality of obsessive-compulsive symptoms and character traits: isolation, undoing, and reaction formation.

Isolation. Isolation is a defense mechanism that protects an individual from anxiety-provoking affects and impulses. Under ordinary circumstances an individual experiences in consciousness both the affect and the imagery of an emotion-laden idea, whether

this be a fantasy or the memory of an event. When isolation occurs, the affect and the impulse of which it is a derivative are separated from the ideational component and pushed out of consciousness.

If isolation is completely successful, the impulse and its associated affect are totally repressed, and the patient is consciously aware only of the affectless idea that is related to it. For example, a patient reported one day in a therapeutic hour that she had had a fantasy of her doctor falling from a seventh story window. In her mind's eye she had seen him hit the pavement and had then observed his crumpled body with jagged bone fragments sticking through lacerated compound fractures and blood oozing from his nose and mouth. "I infer from this," she said in a flat, emotionless tone of voice, "that I am angry at you, but I don't have any feeling like that." This fantasy could not be considered a symptom: it was transient and caused the patient no emotional distress. The defense of isolation had functioned successfully.

Sometimes, however, the isolation is less effective, and the total quantity of energy accruing to the impulse and its associated affect cannot be completely restrained by the repressing forces from entering the patient's consciousness. He experiences a partial awareness of the impulse without fully recognizing its meaning or significance. He may, for example, have frightening and compelling murderous impulses toward strangers or casual acquaintances; here, the impulse makes itself felt as an urge to violent action, but the direction of the urge is displaced from the true object of the patient's aggression to other people in his environment. At the same time, isolation exerts a partial effect by rendering the patient unaware that he is angry, so that he is puzzled, mystified, and disturbed by his compulsions. Or he may be obsessed with images and thoughts of violence and destruction; here again, the energy from the partially repressed impulse gives the thoughts their compelling quality, and the continuing partial functioning of the mechanism of isolation prevents the patient from an awareness that beneath the surface he harbors intense aggression.

The processes that have just been described can be looked at from two points of view: (1) Clinically, the patient's consciously experienced mental events are seen as obsessive and compulsive symptoms. (2) Psychodynamically, they are viewed as a psychological conflict between impulses and controlling defensive forces. The concept of psychological conflict is based on the notion that an undischarged impulse constantly exerts pressure on the individual both for conscious recognition and for discharge. The defenses that operate to control it must, therefore, exert a constantly opposing energy if the impulse is to be maintained under control. That is, a dynamic equilibrium of opposing psychic forces is established. Such an equilibrium may be relatively stable and persistent, as in the case of successful isolation (where no

symptoms are evident) or as in the case of a conversion reaction (where persistent and stable somatic symptoms are apparent). Conversion, in fact, appears to be in one sense a highly effective, if ultimately pathological, defense mechanism. The energy of the impulse is almost entirely bound by the somatic symptom, and the patient is spared the experience of unpleasant affects, as is manifested clinically in the phenomenon of *la belle indifférence*. In the case of the defensive mechanisms operating in the obsessive-compulsive reaction, the situation is different. In this syndrome the equilibrium often proves to be less stable, and the impulse constantly threatens to break through the controls the patient imposes on it. In fact, this tendency of the underlying impulse to escape its bonds is a salient characteristic of the obsessive-compulsive reaction.

Undoing. In the face of this constant threat of the impulse to escape the primary defense of isolation and break free, further secondary defensive operations are required to combat it and to quiet the anxiety that the imminent irruption of the impulse into consciousness arouses in the patient. In the patient who was obsessed by the thought that, by bumping passersby, he had knocked them down and injured them, it was ultimately discovered that he harbored real and angry wishes to push people out of his way when he walked down the street, a conscious awareness of these impulses emerging into the patient's mind in the course of his free associations. However, when he had initially described his obsessional thought, he strongly denied any such urges and was genuinely unaware of any such angry feelings within himself. Nonetheless, the obsessional thought made him very anxious and guilty, just as if he really did have such urges and as if he had in actuality harmed other people. The only way he could reassure himself and quiet his anxiety was by returning to the scene of his supposed crime to make sure that everything was all right. Despite the fact that he knew the whole thing was absurd, he was compelled to this action and remained acutely anxious until he had performed it. The compulsive act, in other words, was secondary to the original obsessional thought.

The anxiety-allaying function of compulsive acts was noted earlier when the clinical aspects of these phenomena were being described. What should be observed here is that the compulsive act constitutes the surface manifestation of a further defensive operation aimed at reducing anxiety and at controlling the underlying impulse that has not been sufficiently contained by isolation. A particularly important secondary defensive operation of this sort is the mechanism of undoing. As the word suggests, it refers to a compulsive act that is performed in an attempt to prevent or undo the consequences that the patient irrationally anticipates from a frightening obsessional thought or impulse. This mechanism was clearly at work in the patient who, whenever he turned off a

light and obsessively thought, "My father will die," would be compelled to turn around, touch the switch, and say, "I take back that thought." With this act he was literally undoing the damage that he feared would result from the initial thought, which arose from an underlying aggressive impulse toward his father.

Reaction formation. Both isolation and undoing are defensive maneuvers that are intimately involved in the production of clinical symptoms. Reaction formation, a third mechanism closely associated with the obsessive-compulsive reaction, results in the formation of character traits rather than symptoms. As the term implies, reaction formation involves manifest patterns of behavior and consciously experienced attitudes that are exactly the opposite of the underlying impulses. Often these patterns appear to an observer to be highly exaggerated and at times quite inappropriate.

A woman of 32, the mother of three small children, revealed that she had had frightening impulses to kill her two older sons. Describing her relationship to her children she said: "I think of my children all the time... I can't punish them. It hurts me to punish them. I just can't do it. I can't face up to hitting them. Even my husband, he'll tell you—even my sisters say the same thing about me. I'm too good to them. I let them run my life, and yet I can't help it... I can't go out unless I buy them a toy... I never went out or anything. I never left them with anybody. I always stayed in the house. Since I had my first boy, anywhere I went I took him with me... I never had any time away from my children. Since I had my first boy [4 years previously], I've never had no time away from them—no time at all." Her habitual and persisting pattern of solicitousness and kindness concerning her children, which even her husband and sisters recognized as being inappropriately exaggerated, was a defensive maneuver designed to control her underlying aggressiveness to them, which was manifest in her murderous fantasies of killing them. Reaction formation is responsible for many of the personality traits characterized by control that go to make up the obsessive-compulsive character.

Psychogenic factors. One of the striking features of patients with obsessive-compulsive neurosis is the degree to which they are preoccupied with aggression or dirt, either overtly in the content of their symptoms or in the associations that lie behind them. This and other observations have led to the proposition that the psychogenesis of the obsessive-compulsive disorder lies in disturbances in normal growth and development related to the anal-sadistic phase. Normally, the impulses associated with the anal-sadistic phase are modified in the oedipal and succeeding stages of development. If, however, disturbances occur in this developmental process, unmodified anal-sadistic impulses remain as components of the individual's psychological makeup.

Ordinarily, these will be controlled and disguised by character traits and may not significantly affect the individual's functioning in the ordinary course of daily living. They remain, however, as fixation points, which may under certain circumstances give rise to difficulties.

Regression. The concepts of disturbances in development and fixation points permit an understanding of the process of regression. In the classical analytic theoretical formulation, regression is the central mechanism in the formation of the obsessive-compulsive reaction and determines that an individual will develop that disorder rather than a conversion reaction. According to psychoanalytic theory, in the conversion reaction the individual *represses* oedipal genital libido, the energy from this undischarged impulse being then *converted* into somatic symptoms. In the obsessive-compulsive reaction, something different occurs. As with the hysterical patient, the obsessive-compulsive patient may begin with a conflict over the oedipal genital impulse, when, for example, this is aroused by an environmental stimulus. However, instead of *repressing* and *converting* this, he employs a different maneuver to avoid the anxiety associated with the genital impulse. He abandons the genital impulses and *regresses* to the earlier anal-sadistic phase of psychosexual development. The return to that earlier stage is facilitated by the fixation points that have remained from the distortions that occurred during his childhood development. By giving up genital urges, the patient is no longer confronted with the conflicts and problems resulting from these urges.

But he has jumped from the frying pan into the fire. As a result of the regressive movement of psychic energies, all the anal-sadistic impulses from the earlier phase of development are reinforced, augmented, and strengthened. Now the pressure of reactivated anal and aggressive impulses toward discharge in behavior arouses new anxieties and new conflicts and requires new defensive operations. Previously, before the regression occurred, reaction formations had been sufficient to control and modify the manageable amount of anal-sadistic energy in the personality structure. Now, with the amount of that energy dangerously increased by the regressive return of energies flowing from the abandoned oedipal position, emergency measures are needed to control the heightened impulses toward anal-sadistic behavior. Prominent among these emergency measures are isolation, undoing, and displacement. As has been seen, these defenses in conjunction with the constantly pressing impulses lead to the appearance of obsessive-compulsive symptoms. And the mechanism of regression sets the stage for the emergence of these symptoms in the form of an obsessive-compulsive reaction.

Psychological results of regression. According to the theoretical model just described, regression causes

an alteration in the quality of the energy with which the psychic apparatus has to deal and in the nature of the defenses controlling it. Three further changes occur in psychic functioning as a result of regression: ambivalence, the emergence of magical thinking, and alterations in the superego.

Ambivalence. Ambivalence is the direct result of a change in the characteristics of the impulse life. It is an important feature of the normal child during the anal-sadistic developmental phase—that is, toward the same object he feels both love and murderous hate, sometimes seemingly simultaneously; at least, one emotion follows the other in such rapid alternation that they appear temporally to exist side by side. In the normal course of development much of the aggression is neutralized, and what remains becomes a desire to win out over the other person rather than to destroy him. As a result, in a mature person, love for the object is dominant, and aggression plays a minor role. When regression occurs, there is a return to the earlier level of functioning, in which ambivalence is a characteristic mode of feeling. Thus, one finds the obsessive-compulsive patient often consciously experiencing both love and hate toward his object. This conflict of opposing emotions may be seen in the doing-undoing patterns of behavior and the paralyzing doubt in the face of choices that are so frequently found in individuals with this emotional disorder.

Magical thinking. In the phenomenon of magical thinking, the regression uncovers earlier modes of thought rather than impulses—that is, ego functions as well as id functions are affected by regression. Inherent in magical thinking is the phenomenon of the omnipotence of thought: the individual feels that, merely by thinking about an event in the external world, he can cause that event to occur without intermediate physical actions. It is this that makes merely having an aggressive thought so frightening to obsessive-compulsive patients. For example, in the young man who had the thought "My father will die" when he turned off a light, there was an anxious concern that his father really would die because of his thought. As has been seen, to undo the consequences of his thought, the patient would compulsively touch the light switch and take the thought back. Here was more magic, partly in the realm of thinking but also in the form of a ritual, a magical act—the touching—that in itself could have no effect on events but was endowed by the patient with unrealistic powers of prevention.

One recognizes in these phenomena a striking similarity to the incantations and rituals that are central to organized magic in all ages and cultures. And one can see the same modes of thinking in the mental processes of primitive peoples, who fear the evil thoughts of others and ward off the bad consequences of such thoughts by apotropaic formulas or who try to influence natural forces (e.g., rain, fertility)

by sympathetic magic. The same kind of magical thinking can be seen in children's rituals and games and fears, which at times reach a degree that is suggestively pathological. For example, a patient of the Swiss psychologist Flournoy described the following episode that occurred in her childhood:

One of my earliest memories concerns my mother. She had been sick in bed for several weeks, and one of the servants told me that she was going to die in several days. I must have been four or five years old. My most cherished possession was a little toy horse made of brown wood, covered with real hair, with a bridle and saddle that I could put on and off as I wished. The horse was kept in a little stable in the hall. I would stubbornly refuse to say my prayers by my bed because Mama was not there to hear them. Instead I began to pray to the horse, kneeling before the little stable and reciting very quickly, without in the least understanding them, the few German phrases of our evening prayer. I was certain that my mother's recovery depended on the faithfulness of my prayers. When her recovery was slow in taking place, a curious thought arose in my mind: that I must sacrifice my horse in order for my mother to get well. The deed was not done all at once, and it cost me dear! I began by throwing the bridle and saddle in the fire, thinking that I might keep the horse when it was thus denuded. I don't remember the exact sequence of events, but I know that with great sorrow I finally broke my horse into little pieces, and when a few days later I saw my mother up and about, I was for a long time convinced that my sacrifice had mysteriously cured her.

Because it occurs both in less civilized peoples and in children, magical thinking is often considered to be a primitive form of mental functioning. The word "primitive" has here a temporal connotation, referring to the fact that it appears early in the evolution of the race or the development of the individual. The theoretical term "primary process thinking," of which magical thought is a manifestation, has the same temporal implication. It is well to remember, however, that such primitive modes of thinking are never entirely eradicated from mental functioning, no matter how mature the individual. They are merely layered over and controlled by more rational and realistically oriented thinking, and they easily reappear when a man dreams, creates, or suffers a pathological regression.

Changes in the superego. The standards and ideals of the mature individual are generally within the limits of potential achievement, and for the most part he lives at peace with his conscience, which pricks him only when he has clearly violated his ethical principles. In the patient with an obsessive-compulsive reaction, the situation is quite different. The number and range of mental and behavioral activities that are taboo are markedly increased, the patient has a heightened self-awareness and self-criticalness, and he becomes harsher in his self-judgments. This is evident in his obsessional concerns over harming or defiling others, in his constant guilty anxiety over what he may have done, and in his incessant need by ritual and compulsive acts to prevent, control, and undo the effects of his forbidden thoughts and impulses. These pathological features can be found to

a certain degree in nonsymptomatic individuals with obsessive-compulsive character traits, but they become markedly exaggerated when such individuals develop a clinical obsessive-compulsive reaction. In the latter case there has been a regression to developmentally earlier stages of the infantile superego—sometimes called the "archaic superego"—the harsh, exacting punitive characteristics of which now reappear in the mental functioning of the neurotically ill adult.

In summary, the psychoanalytic theory of the obsessive-compulsive reaction ascribes the appearance of symptoms to a defensive regression of the psychic apparatus to the preoedipal anal-sadistic phase, with the consequent emergence of earlier modes of functioning of the ego, superego, and id. These factors, along with the employment of specific ego defenses (isolation, undoing, displacement), combine to produce the clinical symptoms of obsessions, compulsions, and compulsive acts.

Learning theory. Practitioners of behavior therapy have evolved techniques of treatment based on the application of the concepts of learning theory to the development of neurotic symptoms. The concern of learning theorists with pathological behavior has been focused primarily on the phobias, the prominence of displacement and avoidance mechanisms in these phenomena lending themselves most readily to an explanation by the learning theory concepts of avoidance conditioning and learning through drive reduction. Very little has been written about the production of obsessive-compulsive symptoms, and the primary attention in the case of this neurotic syndrome has been on the formation of compulsions.

According to learning theory, the obsession represents a conditioned stimulus to anxiety. Because of an association with an unconditioned anxiety-provoking stimulus, the originally neutral obsessional thought gains the capacity to arouse anxiety; that is, a new mode of behavior has been learned. The compulsion is established in a different way: the individual discovers that a certain action reduces the anxiety attached to the obsessional thought. The relief brought about when the anxiety, which operates as a negative drive state, is thus reduced by the performance of the compulsive act reinforces that act. Gradually, because of its usefulness in reducing a painful secondary drive (the anxiety), the act becomes fixed into a learned pattern of behavior.

It is apparent that learning theory provides useful concepts for explaining certain aspects of the obsessive-compulsive phenomena—for example, the anxiety-producing capacity of ideas that are not necessarily frightening in themselves and the establishment of compulsive patterns of behavior. Furthermore, the theory gives a rationale for treatment techniques that are aimed at symptom removal. But in its present form, learning theory leaves many questions unanswered, such as the reason for the obsessional pre-

occupation with ideas that provoke anxiety (one would expect an avoidance of them), the magical quality of the thought processes in the obsessive-compulsive phenomena, and the special prominence of ideas concerning dirt and aggression. At the present time, despite the many gaps and areas of confusion in its formulations, it is the opinion of the author that the psychoanalytic theory provides the most useful, complete, and systematic explanation of the clinical syndrome.

Differential Diagnosis

Generally speaking, the descriptive and structural characteristics of obsessive-compulsive *symptoms as symptoms* generally permit one to differentiate them from other psychogenic symptoms, such as depression, conversion phenomena, and phobias. When, however, one's attention turns to the obsessive-compulsive reaction *as a syndrome*, involving a consideration of the course and patterns of the symptoms in the life of individual patients, it is harder to separate it from other psychogenic disorders, especially the phobic reaction and depression. There are, of course, many patients whose illness fits tidily within the area defined by the characteristics ascribed to it, but there are frequent admixtures of features belonging to other syndromes, and the diagnostic lines cannot be sharply drawn. Although this lack of neatness and order is distressing to the obsessional clinician, it perhaps reflects the fact that psychogenic disorders are not simply the result of localized pathological lesions but are the surface manifestations of complicated psychodynamic processes and regressions to developmentally earlier phases of thought and behavior.

Conditions associated with gross disease of the brain. Obsessive-compulsive-like behavior has been described as occurring in association with temporal lobe lesions or following certain kinds of encephalitis. The facts that only a small number of such cases have been recorded and that the phenomena following encephalitis are more motoric than mental in nature indicate that neurological disease need not be a serious consideration in patients with a typical obsessive-compulsive reaction.

Psychogenic disorders. Although one assumes that there is a neurophysiological substrate to obsessions and compulsions, neurophysiological knowledge is not as yet detailed enough to provide a useful explanation for the clinical phenomena of these or other neurotic symptoms. The obsessive-compulsive reaction remains in the category of illnesses considered psychogenic. The important diagnostic task is to differentiate it from other psychogenic disorders, of which three—the phobic reaction, depression, and schizophrenia—require attention.

Phobic reaction. Some clinicians classify phobias under the heading of obsessive-compulsive phenomena, and it is often difficult to distinguish sharply

between them. In general, the phobic reaction is characterized by anxiety that harm will come to the phobic individual from an external object or situation, and the patient controls his anxiety by avoiding the object. Furthermore, the important mechanisms in phobia formation are displacement and projection, and the underlying conflicts are primarily oedipal in nature. This is, of course, in contrast to the obsessive-compulsive reaction, in which the patient fears that he will hurt others, his anxiety is controlled by compulsive acts and by the mechanisms of undoing and isolation, and the underlying conflicts are predominantly preoedipal in nature.

When the clinical phenomena fit the criteria specified for either one of these two categorizations, there is no difficulty in differentiating them. The two sharply defined categories are, however, but the two ends of a spectrum, and in between fall phenomena that partake of characteristics from both categories. For example, one patient irrationally feared and avoided elevators—not, as it turned out, because he anticipated being hurt by riding in them but because he was afraid of his impulse to push others down the shaft. A young woman with a phobia of streets was afraid of her temptation to yield to her sexual impulses. The bedtime rituals of a young man proved to be a compulsive defense against expressing genital striving through masturbation. In these three examples there is a mixture of obsessive-compulsive and phobic characteristics. It is not, therefore, possible in every instance to make a sharp distinction between phobic and obsessive-compulsive reactions.

Depression. As with the phobic reaction, there are areas of overlap in the obsessive-compulsive reaction and the syndrome of depression. Some 20 per cent of patients with depressive illness have obsessive-compulsive symptoms, and a third have obsessive-compulsive character traits, the figure being even higher if one restricts one's attention to the midlife agitated or involuntal depression that characteristically occurs in obsessional individuals.

Patients who for a period of time have manifested the symptoms of an obsessive-compulsive reaction may go on to develop a typical depression, a phenomenon that was clearly visible in Bunyan's account of his spiritual turmoil. One day, as he was struggling compulsively with his obsessional thought to sell Christ, as had been his wont for some months, he suddenly

...felt this thought pass through my heart, *Let him go, if he will!* and I thought also, that I felt my heart freely consent thereto. Oh, the diligence of Satan! Oh, the desperateness of man's heart! Now was the battle won, and down fell I, as a Bird that is shot from the top of a tree, into great guilt, and fearful despair. Thus getting out of my Bed, I went moping into the field; but God knows, with as heavy a heart as mortal man, I think, could bear; where, for the space of two hours, I was like a man bereft of life, and as now past all recovery, and bound over to eternal punishment... I felt myself shut up into the judgment to come. Nothing now for two years together

would abide with me but damnation, and an expectation of damnation.

Finally, it must be noted that some patients suffer from obsessive-compulsive symptoms episodically, with seemingly self-limiting periods of marked obsessions and compulsions alternating with periods of remission; in other words, their symptoms run a cyclic course like that which characterizes manic-depressive illness.

If one reflects on the example provided by the evolution of Bunyan's disorder from the state in which obsessive-compulsive symptoms predominated to that in which depression was paramount, one can detect a significant difference between these two conditions. In the former hope still exists. Although the evil impulses are attacking with all their forces, the individual still resists. The enemy threatens mightily, but the patient, goaded by anxious intimations of disaster, mans his defenses and maintains his standards in a precarious stalemate. In depression, on the other hand, the walls have been breached, the keep overrun, and the patient has surrendered to the besiegers. The evil has been done, the patient acknowledges his wickedness in guilty despair, and, utterly alone, he hopelessly anticipates the punishment of the damned.

A similar difference is seen in the type of object relationships manifested by patients suffering from these two disorders. The depressed patient tends to retreat from his relationships with others. It is as if the person to whom he was formerly attached were in actuality lost; the libido and aggression once invested in the object are withdrawn, and the psychic energies thus released are directed inward into the patient himself by a variety of psychological mechanisms, for example, identification, turning inward of aggression. In the obsessive-compulsive patient, on the other hand, the emotional tie to other people remains intact, but it has all the coloring of the ambivalence that is central to the obsessive-compulsive reaction.

Despite these striking differences in the structure of the symptoms, and the nature of the patient's relationships, there are areas of overlapping characteristics when one considers the entire symptom complex of these two disorders. As in the case of the phobic reaction, pure depressive disease and the pure obsessive-compulsive reaction represent the two ends of a spectrum that spans an intervening stretch of clinical states with many features shared in common.

Schizophrenia. Because of the irruption into consciousness of magical thinking, there is often a bizarre quality in the thought content of the obsessive-compulsive patient, which raises the question as to whether he is not really suffering from schizophrenia. And yet, despite this characteristic, clinical investigators have pointed out that surprisingly few patients with chronic obsessive-compulsive reactions develop a clearly defined schizophrenic psychosis. The figures run from 3 to 12 per cent and seem to be related in part to the strictness with which the initial obsessive-

compulsive episode has been defined by the investigator.

There can be no doubt, however, from the nature of the clinical evidence that there is some relationship between the two syndromes. During the developing phase of schizophrenia, especially in the acute undifferentiated form, one frequently sees transient and varying obsessive-compulsive phenomena, and these may appear intermittently during the course of a well established psychosis. Occasionally, a clearly schizophrenic episode may appear in the course of a chronic obsessive-compulsive reaction, but it is characteristically mild and transient. The direct transition of an obsessional thought into a delusion is very rarely observed.

Despite these areas of contact between the two syndromes, it must be concluded that the relationship between schizophrenia and the obsessive-compulsive reaction is a more tenuous one than that between the latter and depression or the phobic reaction. No matter how bizarre the content of the patient's obsessional thoughts or how strange his compulsive acts, he usually maintains full contact with reality and is painfully aware of the absurdity of his thinking and behavior. No matter how preoccupied he may appear to be with his symptoms, he does not retreat from his relationships with the people around him, and his affect remains appropriate. The most careful and prolonged observation of his clinical course usually fails to reveal the characteristic stigmata of schizophrenia. Indeed, the presence of a well structured obsessive-compulsive reaction seems to protect the patient from the radical personality disorganization of the psychotic state.

Treatment

Any discussion of the treatment of the obsessive-compulsive reaction must be prefaced by the reminder that the absence of good controlled studies and the paucity of information about the natural history of the disorder severely limit an evaluation of any of the therapeutic measures that have been recommended. Nonetheless, when faced with the suffering of his patient and with the often desperate situation that his symptoms may create for his family, the clinician is forced to do something in an attempt to alleviate if not cure the condition. The treatment measures described in what follows can be considered only as suggestions based primarily on clinical impressions.

Psychotherapy. There can be no doubt that patients respond to the psychotherapeutic maneuvers of the psychiatrist. It is possible, for example, to effect a complete disappearance of compulsive behavior in some patients by the simple device of informing them that the doctor will assume complete responsibility for anything that may happen as a result of their impulses. With this reassurance an occasional patient may abruptly give up a chronic compulsive ritual.

Unfortunately, the improvement usually lasts for only a few hours. The patient begins to doubt the doctor's capacity to assume responsibility and soon returns to his compulsive acts. If valueless as a definitive measure of treatment, this response shows that symptoms can be modified, however transiently, by psychological maneuvers.

It is hard, nonetheless, to make any valid generalizations about the effectiveness of psychotherapy in the management of the obsessive-compulsive reaction. Early in the development of psychoanalysis it was felt that this was the treatment of choice, since, like the conversion reaction, it was a transference neurosis and should theoretically, therefore, respond to psychoanalytic techniques. Individual analysts have seen striking and lasting changes for the better in patients with obsessive-compulsive character neuroses, especially when they are able to come to terms with the aggressive impulse lying behind their character traits. Likewise, analysts and dynamically oriented psychiatrists have observed marked symptomatic improvement in their patients in the course of analysis or prolonged insight psychotherapy.

The decision as to whether such techniques will be helpful cannot be made on the basis of the nature of the symptoms alone. In general, the more chronic and fixed the symptom pattern, the less liable the disorder is to modification by psychotherapy or, in fact, any treatment measures. As is always the case in choosing patients for insight psychotherapy, the criteria for selection depend primarily on factors other than symptoms: (1) the prominence of situational precipitating events, (2) the capacity to relate to the physician, (3) evidence of good relationships with others, (4) stable work patterns, (5) the capacity to tolerate anxiety and depression, (6) the ability to express emotion, (7) intelligence, (8) the ability to be introspective, and (9) flexibility in thinking and behavior.

Supportive psychotherapy undoubtedly has its place in the psychiatrist's armamentarium, especially for that group of obsessive-compulsive patients who, despite symptoms of varying degrees of severity, are able to work and make a social adjustment. The continuous and regular contact with an interested, sympathetic, and encouraging professional person may make it possible for the patient to continue to function by virtue of this help, without which he would become completely incapacitated by his symptoms. Occasionally, when obsessional rituals and anxiety reach an intolerable intensity, it may be necessary to hospitalize the patient until the shelter of an institution and the removal from external environmental stresses bring about a lessening of the symptoms to a more tolerable level. Nor must it be forgotten that the patient's family is often driven to the verge of despair by the patient's behavior. Any psychotherapeutic endeavors must include attention to family members through the provision of emotional support, reassur-

ance, explanation, and advice on how to manage and respond to the patient.

Behavior therapy. In recent years considerable interest has been evinced in the application of treatment techniques based on the concepts of learning theory. As opposed to traditional psychotherapeutic approaches, behavior therapists ignore the complexities of the conflicts and personality disturbances that underlie the clinical phenomena and focus almost entirely on the removal of symptoms. Behavior therapy has been applied primarily to patients with phobias, but a few cases of obsessive-compulsive reactions, reported in the literature, appear to have responded to the techniques of reciprocal inhibition and aversion therapy. The assessment of the value of these treatment measures is beset by the same difficulties that prevail in determining the effectiveness of all psychiatric treatment. The approach of behavior therapy is an interesting one, but it remains yet in the early experimental phase of its development.

Physical therapies. The role of the physical therapies in the treatment of the obsessive-compulsive reaction is limited. There are no drugs that have a specific action on the obsessive-compulsive symptoms themselves, although the use of sedatives and tranquilizers as an adjunct to psychotherapy may be helpful in cases where anxiety is excessive. Likewise, electric shock treatment and antidepressant medication appear to have no direct effect on obsessions and compulsions. But if these symptoms are secondary phenomena to a primary mood disorder, physical treatment may improve them along with the affective disturbance.

Leukotomy has been recommended by some authors as a valuable approach to the treatment of patients with obsessive-compulsive reactions. As a general rule, one wishes to avoid irreversible surgical procedures on the brain in patients with psychogenic disorders, particularly when these, as is the case with many patients with obsessive-compulsive reactions, run an intermittent course. However, there is evidence that the procedure of leukotomy can lessen the intensity of obsessions and compulsions and can diminish the suffering they engender, even if it does not necessarily improve the patient's social adjustment. On this basis, it should be considered in those patients who have a chronic, severe, unremitting obsessive-compulsive reaction that has not responded to any of the less drastic forms of treatment.

Suggested Cross References

For a more detailed account of the psychoanalytic concepts mentioned in this section, see Mack and Semrad's chapter on classical psychoanalysis (Chapter 6) in Area C, on current theories of personality and psychopathology. That same area also contains sections that present alternate viewpoints of psychodynamics. The various psychiatric disorders mentioned in this section—conversion reaction, phobia,

depression, and schizophrenia—are described more fully in Sections 23.2, 23.4, and 17.2 and 24.2, and Chapter 15, respectively. The various treatment modalities, such as psychoanalysis, behavioral therapy, and psychosurgery, are discussed in detail in Area G, on psychiatric treatment.

24.2 NEUROTIC DEPRESSIVE REACTION

MYER MENDELSON, M.D.

Definition

A neurotic depressive reaction is a mood disorder characterized by lowered spirits, reduced self-esteem, self-depreciation, sleep and appetite disturbances,

and a variety of other symptoms. These symptoms most commonly include increased dependency needs or feelings of guilt or inadequacy, fatigue, restriction of interest, difficulty in concentration, and a variety of somatic complaints.

In general, this reaction is differentiated from a psychotic depressive reaction by the absence of certain endogenous characteristics and by a lesser degree of regression. The neurotic depressive suffers only a limited impairment of reality testing and of interpersonal functioning. He is still responsive to his human environment.

This sketchy definition suffices for an initial introduction to the neurotic depressive reaction. However, it implies a much more clearly delineated and generally agreed on picture of this disorder than many papers in the literature would support. It would be misleading to pretend that a consensus exists about the definition and the clinical boundaries of the neurotic depressive reaction. In fact, a vigorous dispute about the very existence of this diagnostic entity has existed throughout its history.

History

Early concepts. Kraepelin in the eighth edition of his textbook subsumed under the diagnosis of manic-depressive psychosis a number of variously named and seemingly separate types of melancholic and manic disorders. He regarded all of these conditions as “merely forms of one single disease process,” which he labeled manic-depressive psychosis. When Kraepelin spoke of a “single disease process,” he was referring to an illness that, despite its manifold symptoms, had a specific and common neuropathology, which admittedly had not yet been discovered.

In the German literature a debate promptly ensued about the alleged unity of this collection of disorders. This debate was gradually resolved in favor of the Kraepelinian synthesis. In this same literature a reactive—that is, psychogenic—type of depression was soon differentiated from manic-depressive psychosis, which was quite generally regarded as being endogenous—that is, biologically and hereditarily determined and independent of environmental stimuli. A certain amount of confusion was soon injected into the situation when it was observed that some seemingly typical cases of manic-depressive psychosis were triggered by psychological events.

In a highly provocative paper, Mapother in England in 1926 challenged the validity of the distinction between neurotic and psychotic depressions. He thought it was “a flat defiance of all relevant experience in medicine” to argue that there was no physical basis for some disorders that were termed neurotic simply because their organic basis had not yet been demonstrated. He asserted that, clinically, “neither insight nor cooperation in treatment nor susceptibility to psychotherapy” would serve to distinguish neurotic from psychotic depressions.

A heated debate promptly ensued in the British literature, mainly defending the legitimacy of this distinction. This defense was based on one or more of the following criteria: (1) spontaneous recovery in the psychotic depressions as compared with the necessity for psychotherapy in neurotic depressions; (2) the presence of remorse in psychotic depressions as compared with the alleged tendency of the neurotic to blame others for his distress; (3) differences in pre-morbid personality; (4) differences in heredity and body build; (5) the absence of diurnal variation of mood in the neurotic depressive; (6) the absence of insight in psychotic depressions; (7) the reactivity, that is, the responsiveness to environmental stimuli, in the neurotic and the absence of this reactivity in the psychotic depression.

An important turning point in this controversy occurred in 1934, when Sir Aubrey Lewis published a detailed clinical study of 61 hospitalized depressed patients and declared himself unable to identify any criteria that would distinguish neurotic from psychotic depressions. He found himself unable to confirm that the criteria of heredity, tendency to spontaneous recovery, diurnal variation of mood, insight, psychogenicity, and reactivity had any invariable or important differentiating significance.

Despite this resounding blow to the separatists, the battle was taken up again in 1940, when the validity of the differentiation between neurotic and psychotic depression was again defended, primarily on clinical grounds. Around this time, a third point of view appeared. It contended that neurotic depressions at one end of the continuum were easily distinguishable from psychotic depressions at the other end of the continuum but acknowledged that there was a borderland area where differentiation was indeed difficult if not impossible.

Much of this debate took place before the days of specific treatment for depression. Since then, persuasive arguments have been advanced in favor of the distinction by appealing to the differential responses of neurotic and psychotic depressives to specific therapeutic modalities—first to electric shock therapy, then to prefrontal lobotomy, and most recently to the new antidepressive drugs.

In the United States, Adolf Meyer, as early as 1908, expressed his impatience with German theorizing about the existence of undemonstrated brain pathology in mental disorders. He disagreed with the value of speculating about hypothetical cell alterations in psychiatric illness. He said:

To realize that such a reaction is a faulty response or substitution of an insufficient or protective or evasive or mutilated attempt at adjustment opens ways of inquiry in the direction of modifiable determining factors and all of a sudden we find ourselves in a live field, in harmony with our instincts of action, of prevention, of modification, and of an understanding doing justice to a desire for directness instead of neurologizing tautology. The conditions which we meet in psychopathology are more or less abnormal reaction types...

Steering clear of useless puzzles liberates a mass of new energy.

Present concepts. The shift of attention to types of reaction, to the impact of the environment on the individual, later supplemented by the psychoanalytic interest in intrapsychic and interpersonal psychodynamics, characterized the perspective on emotional disorders of American psychiatry. The *Standard Nomenclature* of the American Psychiatric Association, with its emphasis on the concept of reaction, embodies this attitude. Both neurotic and psychotic depressions are designated in the American Psychiatric Association *Diagnostic Manual* as, respectively, (1) neurotic and (2) manic-depressive or psychotic depressive reactions.

In British psychiatry, on the other hand, endogenous or biologically determined depressions tend now to be carefully distinguished from reactive or neurotic depressions, although the picture is somewhat confused by some writers, who include under the reactive heading cases of endogenous depression that follow obvious antecedent stress. In these instances, the term endogenous is used to refer to a specific clinical syndrome—characterized by a particular quality of depressive affect, diurnal variation of mood, early morning awakening, etc.—rather than to the cause.

In Germany and Scandinavia at the present time, manic-depressive and involutional depressive reactions are thought of as endogenous and are differentiated from psychogenic neurotic reactions. But there, too, the picture is confused, since some authors regard some cases of endogenous depression as psychogenic.

Thus, in Europe, some authorities cling to the strict definition of endogenous depressions—that is, independent of environmental factors—whereas others feel that some of the depressions they refer to by this adjective may be triggered by psychological circumstances. There is, however, considerable agreement, except among some authorities in England, that neurotic depressions are essentially different from endogenous depressions, which are regarded as constitutional, regardless of precipitating factors.

Insofar as the official nomenclatures are concerned, in Europe as well as in the United States, the separatists, despite some dissenting voices, have clearly won the debate. Neurotic or reactive or psychogenic depressions are generally distinguished from endogenous or psychotic depressions, even though the lines of demarcation are not always clear; both frequently have environmental precipitating factors.

Epidemiology

Since most neurotic depressive patients are not hospitalized, the epidemiological data for this reaction are inadequate. In addition, there are so many disagreements among experienced psychiatrists about the criteria for this diagnosis that such estimates as

do exist in the literature are open to disagreement and skepticism. Under these circumstances, it seems logical not to introduce statistics that are at best uncertain and at worst misleading.

Etiology

Depression basically represents a reduction or breakdown of self-esteem. Self-esteem, in turn, is determined by the balance of libidinal or aggressive cathexes of the self-image. For a psychoanalytic understanding of the etiology of depression, it is necessary to discuss the determinants of self-esteem, that is, the factors that determine the quality of the cathexis or the affective coloring of the self-image.

Factors affecting self-esteem. Among these factors are the following: (1) The self-image. Pathological early development of the self-representation in an unfavorable family atmosphere inevitably affects self-esteem. (2) The superego. An important element in depression is the presence of guilt, which represents the influence of the superego. Discrepancy between one's behavior and one's superego values is experienced as guilt with an accompanying lowering of self-esteem. If the superego should remain fixated in an archaic, infantile, or childish punitive form or if it should regress to this level, then the predisposition to depression is correspondingly increased. (3) The ego-ideal. The more realistic the ego-ideal, the more possible it is for the individual to attain his goals. An overly grandiose ego-ideal inevitably leads to feelings of inadequacy and conflict. (4) The ego functions. The actual abilities and talents of the individual and the smooth integration of his other ego functions determine the degree of his success in living up to the demands of his ego-ideal and therefore also determine the level of his self-esteem.

Thus, love and affection or dislike and criticism from the earliest or the most current love objects, health or sickness, the presence or absence of talents and abilities, success or failure, high standards and conscientiousness, or low expectations and moral indifference all have an effect on one's self-esteem.

Self-image. The self-image is a concept that refers to the psychological (endopsychic) representation of one's bodily and mental self. The synonymous terms "object image," and "object representation" are analogous to self-image and self-representation. Both self-images and object images are conceptualized as being cathected with libidinal or aggressive or neutralized energy. If one's self-image is highly libidinally cathected, one's self-esteem is said to be high.

According to the psychoanalytic model, the gradual acquisition, development, and consolidation of self-representations and object representations are important functions of the ego. One's self-image derives initially from sensations barely distinguished from perceptions of the gratifying part object, the breast, and consequently tends to fuse and become confused with object images. This phase of primary

identification represents a developmental period when the infant is theoretically unable to distinguish objects from itself, when the boundaries between self-images and object images are absent or rudimentary and fluctuating because of the immaturity of the perceptual and cognitive processes.

The self-image is at first not an enduring, firm psychic unit but is made up rather of a constantly changing series of self-representations that reflect the incessant, natural fluctuations of the infantile mental state. In the course of normal development, these early, fluctuating self-images are gradually integrated, organized, and unified into an enduring and consistent self-representation; firm and stable boundaries are established between the self-images and object images; and these images become optimally cathected with libidinal energy. Phrased somewhat differently, in ideally normal development one's identity becomes firmly established, the individual becomes able to differentiate himself clearly from others; he develops an optimal and enduring level of self-esteem; and he acquires the capacity to relate well to others.

Parental influences. For all this to occur, the child requires an atmosphere of parental affection and interest in which he is exposed to tolerable frustrations in manageable doses. An atmosphere in which he is overgratified unduly prolongs the mother-child tie, retards the formation of clear boundaries between self-images and object images, and delays the development of independence and realistic perceptions of the outside world.

As the child develops, an affectionate, accepting parental atmosphere tends to produce a basic self-confidence in one's own lovability; that is, it produces a self-image healthily endowed with self-esteem, representing the reflected appraisal of the important love objects. As the child continues to develop in optimal circumstances, his actual effectiveness, contributed to by his confidence in himself, in turn maintains and consolidates his self-esteem. In other words, feeling loved and esteemed permits the child to develop good feelings about himself and thus permits him to enter into independent interpersonal and educational activities with a minimum of inhibitions. In the absence of frustrations too extreme for the developing child to master, success in these activities then increases and further consolidates his self-regard.

Among the developmental vicissitudes leading to decreased self-esteem and depressed feelings are insufficient parental acceptance and affection, excessive parental devaluation, excessive frustrations experienced prematurely, and a sense of ineffectiveness in one's early social and educational activities. All these tend to produce excessively aggressive cathexes of object images and self-images with correspondingly ungratifying interpersonal experiences and feelings of inadequacy and self-derogation.

From all the above it follows that an important

predisposing factor in neurotic depressive reactions is the quality of the early familial relationship. An unhappy, frustrated, or emotionally deprived childhood spent with undemonstrative or uncaring or punitive parents tends to produce a devalued self-image and a predisposition to depression. Loss of a parent in childhood has also long been recognized as a predisposing factor in depression. During and after childhood, one's self-esteem can also be adversely affected by experiences like illness, disfigurement, unattractiveness, and poor performance in social, educational, or vocational activities. All these circumstances can predispose an individual to react with depression to occasions of loss or guilt or failure. Sometimes the predisposition is so pronounced that the person has a recognizably depressive personality structure characterized by chronic pessimism, loneliness, dissatisfaction, unhappiness, guilt, or feelings of inadequacy.

Variety of causes and reactions. Knowledge of the variety of determinants of self-esteem helps to explain why decreased self-esteem can be experienced in a variety of ways. To put it simply, self-esteem can be decreased and depression can be present because one feels lonely and unloved, unworthy or bad or guilty, or unsuccessful, or inadequate or inferior. And depression can be precipitated by the failure to obtain or by the loss of love or emotional supplies; by engaging in behavior or by experiencing feelings, such as sexual or aggressive ones, that cause one to feel guilty or unworthy; or by failure in the pursuit of goals, whether realistic or unrealistic.

A neurotic depression, once established, may involve a regression to earlier, ordinarily repressed self-representations or components of the self-image. One's self-image, even in ideal circumstances, is never an entirely homogeneous, integrated structure. Ordinarily, except in individuals who are chronically depressed or who are burdened with enduring and conscious feelings of loneliness, guilt, or inadequacy, devalued aspects of the self-image tend to be repressed. When a person becomes depressed, these ordinarily repressed components of the self-representation emerge and become predominant. If the regressive process is sufficiently extensive and sweeping, the depressive reaction is psychotic in character.

Other psychoanalysts' concepts. From the time of Freud's important paper, "Mourning and Melancholia," an association has always been assumed between aggression and depression. According to the formula, aggressive feelings meant for the disappointing love objects are redirected against the self and produce feelings of guilt, unworthiness, and depression. The patient blames himself for the characteristics of the disappointing object. As Jacobson has shown, the confusion and identification between the object representation and the self-image, which was earlier taken to be a characteristic feature of depression, actually represents a regressive dissolution of

the boundaries between the self-image and object images. This type of regressive fusion of self-representation and object representations is the hallmark not so much of a depression as of a psychotic process. Self-directed aggression in the context of this regressive process was prematurely taken to represent the paradigm for all depressions.

More recent psychoanalytic studies of depression have shifted the emphasis to the loss of self-esteem as the central psychological problem in depression. In this perspective, the melancholic introjection that produces the loosening of boundaries and the confusion between self-directed and object-directed aggression is seen as a late defensive or restitutive maneuver in a psychotic depression.

Certain psychoanalysts of the nonclassical schools have also paid special attention to the vicissitudes of self-esteem. Although Horney did not discuss specific clinical syndromes in her major works, she nevertheless analyzed the problems of self-esteem and the self-image in great detail. She, in fact, considered them the central issues in personality development. Sullivan did consider and describe certain diagnostic entities, but there is no specific discussion in his published works on the neurotic depressive reaction. However, his ideas on psychodynamics are characterized by the view that the attempt to maintain self-esteem is one of the chief security operations of what he referred to as "the self-system."

Clinical Description

A neurotic depressive reaction usually begins as a reaction to a loss or to a failure of some kind. The depression may develop suddenly or slowly, over some period of time. The loss may be the death of or a disappointment by a loved object. The depressive reaction may be triggered by a failure to live up to one's standards or to achieve one's personal or vocational goals. Whatever the immediate cause, the depression is characterized by a loss of self-esteem. The clinical picture in a neurotic depressive reaction may be of varying degrees of severity.

Psychological symptoms. The patient ordinarily complains of a disturbance of mood. Depression may be exceedingly painful to the individual. In describing this change in his spirits, he tends to use words like "blue," "sad," "unhappy," "hopeless," or "depressed." He often reports a reduction or loss of interest in his usual activities and may complain of difficulty in concentration. These symptoms may not be severe enough to interfere with his work, although in severe cases the patient may find it difficult to carry on and may require hospitalization.

Further inquiry into his feelings and thoughts usually reveals that the patient feels deprived of emotional support, that he feels empty and lonely, guilty and unworthy, or inferior and inadequate. He may express any combination of these feelings. He is usually self-critical and self-derogatory but is not

necessarily so. A patient may occasionally complain of loss or loneliness or feelings of emptiness without expressing or experiencing any feelings of self-criticism.

Although impairment of reality testing is a major characteristic of psychotic states, the perception of reality does not remain unaltered in neurotic depressive reactions. Nor is this surprising, since reality testing is not an all or none phenomenon that is either present or absent in emotional reactions. It is an ego function with varying degrees of impairment. Even the average normal human being develops a subtly individual perspective on reality that is a consequence of his unique life experience. There are, furthermore, no objectively calibrated models of reality by which to measure precisely the accuracy of someone's reality testing. The physician depends on his intuitive clinical judgment.

Since even normal fluctuations of mood have a considerable effect on the way that a person experiences himself and the world, it is not surprising that neurotic depressive reactions generally produce perceptible alterations in the patient's critical judgment of himself and others. In a depressed mood one exaggerates or distorts some aspects of reality and overlooks or denies other aspects. Denial and distortion of various facets of reality are invariably found in depressed states.

The patient often craves emotional support of one kind or another, such as affection, reassurance, sympathy, or attention. The patient's complaints may serve the purpose of eliciting sympathy and support. Frequently, however, his complaints are so hostile or peremptory or his needs so insatiable that he frustrates his own purpose by irritating or alienating his potential sources of support.

The presence of suicidal thoughts are to be looked for in every depressed patient. They are rarely absent. But it is the task of the clinician to distinguish between occasional feelings that life is not worth living; specific thoughts of suicide; and rare, frequent or continuous, and actual, suicidal plans.

Physical symptoms. In appearance, the patient may look obviously unhappy and dejected with strained and drawn features. He may look tired and discouraged or even apathetic. There is usually a lack of vivacity or color in his speech and manner. There may, however, be no evidence of any of these signs, even if the patient is quite depressed. The neurotic depressive may complain of fatigue. A sleep disturbance is another frequent finding. The patient may have difficulty falling asleep. He may sleep fitfully. Occasionally, he has no trouble getting to sleep but awakens early in the morning, although this pattern is more common in psychotic depressions. Some patients seem to escape into sleep to avoid their distress and preoccupations.

Appetite may be impaired, but this is not a universal finding. Some patients resort to eating as a solace

or substitute gratification during periods of depression. Almost every depressed patient experiences an intensification of oral cravings during periods of depression, but only in certain patients does this assume the form of increased eating.

Schizoid depression. This subtype of neurotic depressive reaction has not received the notice it deserves, although there have been occasional references to it in the English literature, and the predisposing personality type has been described in several papers. Patients with this kind of depression ordinarily describe themselves as empty, lonely, yearning, hungry, and perhaps hopeless. This quality of depressive affect is thought to be related to early deprivations experienced in the context of unsatisfactory parental relationships. Patients with this kind of depression are found to possess a self-image that is fundamentally libidinally undernourished and that represents a defect in ego development.

The depression associated with this type of self-image usually represents an intensification of a feeling state that is chronically present and that is very much a part of the patient's personality structure. In terms of its clinical features it is to be differentiated from depressions that are experienced by the patient as feelings of inadequacy and guilt and that psychoanalytically can be conceptualized as reflecting aggressive tensions between the ego-ideal or superego and the self-image.

Patients with this lonely, empty type of depression are often referred to as schizoid, a term that applies to the defensive techniques of detachment, non-involvement, and intellectualization that many such patients adopt. An intensification of the schizoid state into a depression usually occurs following the loss of, or the failure to obtain, a love object rather than after experiences of guilt or failure.

This empty, hungry kind of depression often presents as a depressive equivalent rather than as an overt depression. The patient may complain of an eating disorder or of an addiction or drug habituation problem or of alcoholism instead of the underlying depressed state that has led to these substitute gratifications. However, these alternative manifestations of oral regression may coexist with conscious depressive affect.

Differential Diagnosis

Since depressive affect is not confined to those psychiatric conditions categorized as depressive reactions, the physician may occasionally have to decide whether the presence of this affect in a mixed clinical picture warrants the diagnosis of neurotic depressive reaction.

Very often, some degree of depression is present in an anxiety reaction and other psychoneurotic disorders. In such a case the clinician makes his diagnosis on the basis of the predominating symptom, although he may wish to direct attention to the secondary

symptom if it is sufficiently prominent; for example, he may designate it "anxiety reaction with depression." In this instance, "depression" is not a diagnosis; it is merely a descriptive term. The American Psychiatric Association's *Diagnostic and Statistical Manual* clearly states that "only one type of psychoneurotic reaction will be used as a diagnosis, even in the presence of symptoms of another type."

Depressive affect may also be present in a schizophrenic reaction, especially in the category labeled "schizophrenic reaction, schizoaffective type." Here the determining criteria for the diagnosis are the schizophrenic signs and symptoms. If a schizophrenic thought disorder or bizarre behavior is present, the schizophrenic rather than the depressive diagnosis is indicated.

Depressed conditions, sometimes difficult to distinguish from neurotic depressive reactions, may be present after the administration of certain drugs. Reserpine, or the steroids, for example, may produce an emotional reaction characterized by depression. This type of depression should be regarded as secondary to the use of the particular medication rather than as a primary neurotic depressive reaction.

A variety of physical conditions may give rise to depressed states that are sometimes difficult to distinguish from functional depressive reactions. A depressed mood may occur in a variety of hormonal disequilibria, such as thyroid dysfunction, the menopause, and adrenal cortical dysfunction. Malnutrition and electrolyte disorders may produce depressed states. Central nervous system disorders, such as multiple sclerosis and occasionally brain tumors, may also produce depressive symptoms.

Psychotic affective reactions. The most common diagnoses from which the neurotic depressive reaction must be differentiated are the psychotic affective reactions. The history of the patient tends to be different in these various kinds of depression. Although the descriptions in the literature of the premorbid personalities are not altogether uniform, one can say that the neurotic depressive tends to have a neurotic history. He has a history of varying degrees of maladjustment, characterized by symptoms of anxiety or tension or by mild depressive upsets of short duration. Such a person may have always been a worrier, with poorly established and fluctuating levels of self-esteem.

The manic-depressive's premorbid personality is often one that is superficially well adjusted, warm, outgoing, confident, and not troubled by minor stresses and strains. Frequently he is quite insensitive to the subtleties of interpersonal transactions. The type of person who develops an involutional depressive reaction may, on the other hand, have been a compulsive, hardworking, somewhat introverted person with high standards of achievement, not necessarily warm or friendly. He is frequently the kind of person who is a pillar of his community.

Most British and European as well as many American psychiatrists believe that there is a constitutional difference between the neurotic and the psychotic depressive. Many psychoanalytic authorities, such as Freud and Jacobson, have subscribed to the idea of as yet unknown constitutional, endogenous, or physiological processes in psychotic depressions.

The manic-depressive usually has a history of depressive or manic episodes, occurring in attacks, with periods of well-being in between. The involutional patient tends to get sick in his later years after a lifetime of freedom from depressive illness. Although it has been traditionally held that the involutional has only one depressive illness in his life, in actuality many patients have one or more recurrences.

As for the symptomatic differences, the psychotic depression is ordinarily accompanied by a much more profound disorganization than the neurotic depressive reaction. The psychotic depressive appears to have a much more profound depression than the neurotic. Some writers point to a difference in the quality of the depressed mood, difficult to describe but alleged to be easily recognized by the patient himself. The patient with the psychotic or endogenous depression experiences his depression as something befalling him from the outside, slowing him down, and interfering with his thinking processes and his zest. These authors describe the neurotic depressive, on the other hand, as experiencing his depression as a mere intensification of lowered moods with which he has been familiar most of his life.

The psychotic depressive tends to experience a much greater deterioration in his relationship to reality. Some alteration of reality testing occurs in a neurotic depressive reaction, too, but the neurotic patient is usually aware that he is distorting or exaggerating the situation. He is aware that the depressive mood is somehow subjective in nature and that, although the self and the world are seen differently from before, things have not actually changed. The patient is still to some extent open to alternative perceptions of himself and others. Indeed, the less he is able to distinguish his mood-determined perspective from the objective situation, the closer to a psychotic state he is. When the psychotic depressive expresses delusions of sinfulness, guilt, or inadequacy, there is no difficulty in making the diagnosis.

The psychotic depressive is likely to show moderate or severe retardation, which he may experience as difficulty in thinking, concentrating, and moving. To the observer this appears as a slowing down of speech, thought, and movement. The patient may sit dejected and immobile for long periods of time, and in severe cases the retardation may be so overwhelming that it may be difficult to distinguish the depression from a catatonic state. This type of retardation is not common in neurotic depressions.

Also not ordinarily present in neurotic depressive

reactions is the agitation that the psychotic depressive may exhibit instead of retardation. This is characterized by restless pacing and perhaps hand wringing and by repetitive complaints or expressions of delusional self-depreciation or hypochondriasis.

Psychotic depressive patients tend to have a specific kind of sleep disturbance, characterized by little difficulty in falling asleep and by early morning awakening, sometimes as early as 2 A.M., although patients with less severe cases awaken around 5 or 6 A.M. The neurotic depressive, on the other hand, tends to have difficulty falling asleep or, alternatively, he may escape into long hours of sleep.

The psychotic depressive characteristically exhibits a diurnal variation of mood, at least before he becomes too severely depressed. He tends to feel worse in the morning when he awakens and best in the late afternoon or early evening. This pattern is ordinarily not present in a neurotic depressive reaction.

The mood of the neurotic depressive tends to respond to what goes on around him. He may cheer up when something pleasing happens to him or when someone offers sympathy or affection. The psychotic depressive tends to be uninfluenced by such events. His mood may be impervious to environmental stimuli.

Although there is ordinarily no difficulty in distinguishing a neurotic depressive reaction from a severely retarded, agitated, or delusional psychotic depression, there is a type of depressive reaction that is much more difficult to distinguish from a neurotic depression. In this type of depression no obvious retardation or agitation may be observed. The patient expresses no delusional ideas. He may not even complain of being depressed but may, instead, speak of being fatigued or of having lost interest in his work or in his former pleasures or hobbies. He complains of difficulty in concentrating and sometimes of inability to go on with his work. He exhibits early morning awakening and diurnal variation of mood.

Such a patient may superficially resemble a neurotic depressive reaction by virtue of his apparent grasp on reality and because of the absence of florid self-depreciating or behavioral phenomena. However, there may be no obvious precipitating circumstances; the patient may not be appropriately responsive to external events; and there may be present the endogenous signs and symptoms mentioned above.

This kind of depression is variously referred to in the literature, especially the European literature, as a simple or atypical or pseudoneurotic endogenous or manic-depressive psychosis. Sometimes, in recognition of the absence of obvious psychotic manifestations, this kind of depression is referred to as a nonpsychotic or mild endogenous or manic-depressive reaction.

Prognosis

Neurotic depressive reactions usually remit spontaneously without treatment unless suicide intervenes. However, their course may be fairly prolonged, and

the patient remains susceptible to another episode of depression.

With treatment, prognosis is better as far as the duration of the depressive episode is concerned. With medication the depression sometimes lifts within a few days. One of the goals of psychotherapy is to so modify the personality structure of the patient that the predisposition to subsequent depressive episodes is reduced.

Management

Initial evaluation. The first task of the clinician is to estimate the depth and severity of the depression and the danger of suicide. If there is evidence of a suicidal risk, the patient should be hospitalized.

The criteria for the likelihood of a suicidal attempt include the depth of the mood disorder, feelings of hopelessness, and the presence and quality of suicidal thoughts, fantasies, or plans. A criterion that has more to do with the personality structure or the ego functions of the patient than the depression itself is related to the patient's history of impulsivity or to the degree of control he has over his impulses.

The life-long empty, lonely kind of depressed patient may at some point decide that, unless something can be done to make his life seem worthwhile, he will commit suicide. Here the clinician is faced not with the management of a depressive episode but of a long, enduring, lonely, or depressed state. A brief period of hospitalization will not abolish the danger of suicide. Unless the inner emptiness and desolation are relieved, the patient may at any point decide that he has had enough distress. And it is impractical to hospitalize a patient like this for the rest of his life.

After the initial evaluation, a depressed patient should be told that he is suffering from an illness and not from a moral lapse, that there is treatment available for his condition, and that his prognosis, in general, is good. The clinician should avoid admonishing or advising the patient to cheer up, to try harder, to stop complaining, or to cease being so absorbed with himself. The probabilities are good that the patient's relatives and friends have been very generous with advice of this type, often to the patient's despair.

When the patient is suicidal, the psychiatrist should hospitalize him and, depending on the particular circumstances of the case, may wish to pursue more vigorous treatment, such as antidepressive drugs or electroconvulsive therapy. Although neurotic depressives do not ordinarily respond to electric shock, it is sometimes resorted to with hospitalized suicidal patients.

Psychotherapy. The treatment of choice in neurotic depressive reactions is psychotherapy. Because of the particular nature of this reaction and because of the possibility in some depressed patients of a psychological shift in the direction of suicide, the psychotherapy of depression should occur in a setting of

therapeutic support appropriate to the nature and depth of the depression.

Unlike some other psychiatric disorders, a depressed affect is something with which most clinicians, like the rest of the human race, have probably had some experience. It is ubiquitous. Therefore the therapist can ordinarily empathize with the neurotically depressed patient, even though the latter may manifest a depth of depression that the clinician may never have experienced.

An empathic, understanding, and nonexhortatory attitude on the part of the physician is a prerequisite in the treatment of this condition. The clinician who treats depressives must be able to tolerate the intense dependency needs of many of these patients and the often monotonously recurring discouraged complaints. He must be sensitive to certain reactions in himself that may interfere with an effective therapeutic relationship. The patient's incessant complaining may eventually irritate or anger the therapist. It may also, especially if the patient does not seem to be improving, threaten his sense of effectiveness. It may then produce a defensive avoidance reaction on his part or perhaps an attitude of antagonism or blame, as if it were the patient's fault that he was not getting well despite all that the therapist is doing.

Aggression. Freud's "Mourning and Melancholia" directed attention to the aggressive components in a depressive reaction. He illustrated with clinical examples the turning of aggressive feelings away from the disappointing love object onto the self. This insightful observation has given rise to a tendency, especially among inexperienced therapists, to treat all depressed patients by trying to get the aggression out, that is, by attempting to make the patient aware of hostile feelings and encouraging him to express them.

This therapeutic formula fails to take into consideration several important elements in the psychodynamics of depression. In the first place, the patients that Freud wrote about were melancholics, that is, psychotic depressives. The pathognomonic introjection that Freud described represents essentially a psychotic failure to maintain the boundaries of the self-representation rather than a typically depressive mechanism. It is the fusion of self-images and object images that causes the melancholic to berate himself in terms that are more appropriate to the disappointing object.

Neurotic depressives do not undergo this psychotic regressive process. They do not confuse themselves with the object. And although the self-image may, in psychoanalytic terms, be aggressively cathected by the superego, the aggression here refers to instinctual energy, an entity belonging more in the realm of metapsychological conceptualizations or theoretical models than in the world of hostile feelings.

Nor is it universally agreed among psychoanalytic authorities that aggression, even in the form of ten-

sion between the superego and the self-image, plays a universal role in depression. Some analysts see depression entirely as an ego phenomenon, not involving aggressive cathexis at all. However, even analytic writers who do not question the role of aggression and the superego in depression visualize some types of depression as resulting from a defect in ego development secondary to early disturbed parental interactions. This ego defect results in a self-image inadequately endowed with libidinal cathexis. It results in an individual who chronically feels empty, lonely, and yearning for affection and closeness. Oversimplified, his problem is not that he is inadequately expressing his hatred of others; his problem is that he feels starved for love, closeness, and self-respect.

To indicate to such a patient that his illness derives from inadequately expressed feelings of hostility is only to depress him further. Not only is he likely to feel misunderstood, but his self-esteem is likely to sink even further because, in addition to all of his other troubles, his therapist seems to be telling him that he is also a hateful, angry, hostile person.

Even in those patients where seemingly unavoidable resentful and hostile feelings are not being expressed, it is often a therapeutic error to focus on these feelings too early. Frequently, the patient's inability to express or experience these feelings stems from his own sense of unworthiness. It requires a certain amount of self-respect before one can feel resentment at some injury. To experience and express hostility, one's self-esteem must first be restored.

Tasks and goals of therapy. Since a depressive reaction is essentially an affective state characterized by a loss of self-esteem, the therapeutic task is to examine the circumstances of this loss and of the factors that predispose the patient to it. The goal of treatment is not only the alleviation or resolution of the depressive symptoms but also the development of the kind of insight that will give the patient greater immunity to subsequent recurrences and that will permit a more successful adaptation to life.

Therapy involves one or more of the following tasks.

1. Where the patient is empty and lonely, the therapeutic task may be to uncover the factors that prevent the patient from achieving the kind of object relationships that are necessary for adequate self-esteem. This may lead into the following areas: helping the patient identify his needs, for not every person is consciously aware of his interpersonal and affectional needs; the examination of defensive maneuvers that tend to isolate the patient; the identification of self-defeating patterns of relating to members of the opposite sex. To achieve these goals often requires a long period of intensive therapy, especially if the patient has evolved complex or stubborn defenses or personality patterns that interfere with the gratification of his needs.

2. Where the problem is one of guilt, the thera-

peutic task may involve the modification of an unrealistically harsh conscience, that is, of a superego retaining much of its early unmodulated punitiveness, somehow insufficiently affected by the usually softening influence of the developmental process. Although guilt is probably more characteristic of psychotic depressions, it is by no means unusual in the neurotic depressive reaction.

3. Where the patient's reduced self-esteem is a consequence of an unrealistic feeling of inadequacy, the therapeutic goal will be to help the patient acquire a more realistic perspective on his abilities and talents. This usually includes the modification of an unrealistic ego-ideal in the direction of a more reasonable level of aspiration.

Medication. Since the neurotically depressed patient usually has trouble falling asleep, he is grateful for a nighttime sedative that spares him hours of tossing and turning. It is best to prescribe this medication in small quantities in order to minimize the suicidal risk.

The anxiety that is often present in a neurotic depressive reaction can be relieved by the administration of one of the milder tranquilizers.

The amphetamines are often useful and sometimes gratifyingly efficacious in lifting the spirits in a mild depression. When antidepressive medication is resorted to, the amphetamines should probably be tried before prescribing the newer antidepressive drugs.

Although antidepressant drugs appear to be more effective for psychotic depressions, they do have a place in the treatment of neurotic depressive reaction. However, there is still considerable uncertainty and controversy about the exact indications for use and about the criteria for choosing among the drugs available.

Chemical relief of the depressed mood should not imply abandonment of the psychotherapeutic goals discussed above.

Neurotic depressive reactions ordinarily do not respond to electroconvulsive therapy.

Chapter 25

Personality Disorders. I: Trait and Pattern Disturbances

25.1 TRAIT AND PATTERN DISTURBANCES

EUGENE B. BRODY, M.D.

LINDBERGH S. SATA, M.D.

Introduction

"Personality" has generally been used as a global descriptive label for the totality of a person's objectively observable behavior and his subjectively reportable inner experience. The wholeness of an individual described in this way represents both the public and the private aspects of his life.

The word "personality" may have appended to it certain qualifying adjectives with psychiatric significance, such as "passive" or "aggressive," or words that are not freighted with pathological overtones, such as "ambitious" or "religious" or "friendly." A coherent series of such qualifications making up a personality diagnosis implies certain predictions about how a person will behave under given sets of circumstances. It suggests the form that psychiatric illness may assume, should it develop. It offers the physician clues about how a man will react to physical illness or disability and about how he may be approached for treatment purposes—whether that treatment be conducted mainly through the use of drugs, surgery, or interviews. Whether used as a psychiatric diagnostic term or as a folk description, the personality label has value for the physician who must deal with the individual so described.

Personality formation. Personality diagnosis is based on a concept of behavioral categorization that takes into account the interplay of currently active psychological tendencies and that depends for its typology on varieties of formative developmental experiences. Such a concept must be concerned with the learning of environmentally useful responses. A man's personality reflects his techniques for getting along

with people and things; or, in the sense of Hartman's definition of adaptation, it represents his usual behavior in the process of establishing and maintaining a stable, reciprocal relationship with his human and nonhuman environment. It also reflects the nature of his psychological defense system, the mechanisms—called "ego defenses"—that he automatically and customarily employs in order to maintain his intrapsychic stability.

According to psychoanalytic theory, these defensive and adaptive techniques are to an important degree a function of the level of psychosexual development an individual has achieved.

The importance of early development may also be described in other terms, most of which deal with the influence of society and culture, mediated through child-rearing patterns, on adult behavior. A wide range of investigations has suggested the presence of modal or basic personality patterns that emerge in certain cultures. These are determined at least in part by the universality within the culture of parental methods of dealing with the child's basic needs, such as eating, excreting, sleeping, and moving; with his expression of thought and, especially, of feeling; and with the crises that accompany the maturational sequences and the societally determined shifts in context, such as the shift from the family to the school. Such modal personality organizations are also determined by patterns of sanctioned and prohibited adult behavior and by related factors that prevail within the culture.

Within societies, recent research emphasis has focused on the impact of life in the various social class strata. Particular attention has been paid to the types and frequency of adult models—fathers, for instance—available to children in the different classes; to the effect of belonging to discriminated against, socially visible minority groups; to the need to learn differing communication systems within the family and in the larger society; to the influence of lack of novelty and lack of emotionally significant intellectual stimulation in the earliest years, resulting

in a limited repertory of verbal and other cultural symbols; and to the premature activation of adaptive mechanisms, resulting in an apparently rapid acquisition of the ability to think concretely at the expense of being able to think abstractly and imaginatively. These factors—the frustrations imposed by poorly developed intellectual and interpersonal techniques, the establishment of goals without the means of achieving them, and the paucity of channels for need gratification—all influence the ways of thinking, feeling, and acting, that is, the set of responses that are called personality.

A major feature of this response organization is its stability. It reflects a compromise between the pressures of the inner drives, the claims of the superego or unconscious conscience, and the demands of reality. Such a compromise permits the gratification of certain wishes, reduces inner conflict, and may involve the regular endurance of some degree of discomfort or punishment as the price of gratification. For certain individuals the discomfort itself may acquire primary gratifying significance.

Ego-syntonic and ego-alien behavior. A necessary consequence of this view is that the ways of behaving that constitute most of a person's daily activities are ego-syntonic. They are experienced as normal, natural, or part of him. They are not experienced as special or strange because of their very usualness or pleasurable or rightness. This contrasts sharply with the experience of neurotic tension-laden symptomatic behavior as ego-alien, foreign, irritating, and to be gotten rid of.

The concepts of ego-syntonic and ego-alien imply that the diagnosis of a disordered or abnormal personality is fundamentally social in nature. Since the behavior concerned is not experienced as symptomatic or uncomfortable by its possessor, it must be labeled as deviant by others who experience it as destructive, frightening, or nonconforming. The primary subjective experience of the personality-disordered person does not lead him to seek help for himself. When he himself is motivated to search for treatment or to effect a change in his life style, it is usually because of secondary anxiety, remorse, or other tension stemming from the social repercussions of what he has done. He may learn from the repeated criticisms of others or from the repeated experience of defeating his own goals or of alienating his friends and family that something is indeed wrong with him. But this learning is, to a considerable degree, abstracted from his feeling of psychological reality. It is not sufficiently invested with emotion to result in his abandoning the undesired patterns of acting, thinking, and feeling, particularly as they influence relations with others. It is the *others* who make emotionally invested diagnoses of social deviance and press for modification.

The seeming clarity of this model of *self-diagnosis* for the neurotic and *other-diagnosis* for the individual whose personality is disordered (aside from the mo-

tivating force of socially inspired discomfort) will not usually withstand close examination. Most individuals do not present themselves in pure culture, with ego-syntonic conflict solutions and anxiety-free lives. On the contrary, intimate knowledge of the individual usually reveals a number of persistent unsolved conflicts involving unacceptable impulses and associated tensions that are dealt with in more or less unsatisfactory ways by neurotic mechanisms. Such extensive information tends to require two diagnoses: the leading diagnosis, depending on what brought him to psychiatric attention in the first place, may be a personality diagnosis; the other diagnosis may be of a neurotic or, in some instances, a psychotic reaction. The patient who comes to a doctor under social pressure with a life style indicative of personality disorder may, when given the opportunity, offer complaints of an essentially neurotic variety. On the other hand, many patients who refer themselves for help because of complaints of nervousness, depression, or bodily discomfort for which no organic basis was found may impress the psychiatrist as exhibiting mainly a picture of personality disorder in spite of their neurotic difficulties.

Another implication of the concepts ego-syntonic and ego-alien is that it is possible for an ego system to evolve that facilitates the relatively conflictless gratification of wishes resulting in interpersonal difficulties or the defeat of privately important goals. It may promote the use of defense mechanisms and adaptive maneuvers that effectively paralyze constructive action, produce personal alienation or isolation, and make it impossible for an individual to learn from rewards or punishments. These ways of behaving, facilitated by modifications in the ego system, are perpetuated in spite of the social repercussions they elicit. The constantly reinforcing effect of the pleasure, tension discharge, or security they afford outweighs the pain, loneliness, or frustration that may occasionally be suffered.

The avoidance of intrapsychic conflict requires actual or symbolic wish fulfillment as early as it can be achieved during adaptation. However, the adaptive process, in which the analysis and synthesis of incoming data ultimately result in the acquisition of new responses (learning), is impaired by early and effective tension discharge that may remove the need to discover new responses. During psychotherapy, the developing insight itself—that is, the early phase of learning as it occurs during treatment—evokes discharge behavior through action, waking fantasy, or dream. In these instances, a type of intrapsychic stability is achieved at the expense of the person's ability to solve new interpersonal problems and to acquire new responses. This type of intrapsychic stability, based on what may be conceptualized as an ego system so distorted as to minimize psychological tension, is fundamental to the ego-syntonic quality of behavior in most personality disorders. Its relative

stability reflecting the integration of conflict solutions into a structural whole contrasts with the lack of conflict resolution of the neurotic reaction. In the latter, high levels of tension, associated with chronic partially successful efforts to deal with unacceptable impulses through a defense system with repression as the cornerstone, produce feelings, thoughts, and actions subjectively experienced as foreign, upsetting, or irritating, that is, ego-alien.

Treatment. These considerations suggest the difficulties that appear in the course of psychotherapy with personality-disordered patients. They are people who, in the first place, tend to lack any fundamental motivation for change. Increases in tension, such as those that occur during long term psychotherapy, tend to result in discharge phenomena before useful insights can be achieved. The positive pleasure rewards from the deviant behavior tend to outweigh the socially incurred suffering that may follow.

The psychotherapist, concerned with his patient's motivation, may decide to concentrate on the secondary anxiety or distress following the social condemnation of the latter's behavior. This usually provides no more than a very weak lever. Patients whose disorders take forms that evoke particular punishment may even wish to remain in contact with a therapist as an "out" in case of legal difficulties.

The therapist may decide not to question the presence of motivation if the patient has referred himself. He then approaches the problem as he does any other, dealing with the material brought to him by the patient in a relatively nondirective manner. In this instance a repetitive recital of complaints against others or a sterile recounting of the interpersonal reflections of his life style is possible.

The therapist may deliberately focus on the neurotic aspects of the patient's problem or, in the case of certain isolated personalities, on the elements of loneliness, hopelessness, or despair that may be identified. In this approach the socially deviant behavior may be ignored until later in treatment. This offers at least the possibility of enlisting the patient's interest or even temporarily increasing his discomfort while establishing a relationship so that with greater motivation he may avoid the temptation of escaping from therapy entirely.

The usual forms of individual treatment may be eschewed in favor of a group approach that emphasizes the patient's similarities and differences from others and offers him the opportunity to form relationships and learn new interpersonal techniques. Many psychiatrists feel that group treatment is particularly useful for those characterologically disordered patients who can tolerate such contact with others. Variants of this, such as therapeutic social clubs, milieu manipulation in hospitals, conjoint family therapy and even experiments in group living and working, are all regarded with considerable interest by workers in this area.

Perhaps the only general principle that may be offered the therapist is that of flexibility. He is dealing with a patient whose motivations are mixed, whose ability to relate to others is impaired, who has found important solutions to inner problems in the very patterns the therapist threatens to take away from him, and whose complaints have no discrete beginning in the sense of illness but are part of the warp and woof of his life history and his personal identity.

This patient will, if possible, divorce his therapy from the social reality of life. He is ready to see the psychiatrist as a neutral figure who neither desires nor tolerates close involvement with others. He needs models from whom he can learn, people with whom he can identify, and consistent reliable feedback about the nature of his emotional impact on others. This means that the psychiatrist cannot retreat to dependence on a model of neutral passivity. He must be prepared, if necessary, to enter into the actual life of the patient, while remaining fully aware of the possibility of being manipulated. He cannot decide to avoid contacts with the family or friends of the patient. But in every instance he must understand that it is essential for the patient to perceive him as being on his side.

Personality-disordered patients place perhaps the greatest demands on psychotherapists. The rewards for continued devoted work with such patients have been relatively small to date. The tendency for the therapist to become annoyed, discouraged, or preoccupied with his own therapeutic impotence is great. The fact that these patients are more easily seen as bad, stupid, or childish than as disordered imposes special difficulties on those who work with them. It also suggests the need for constant experimentation with new educational or social methods of treatment with which to supplement or perhaps replace the more traditional but often ineffective one-to-one approaches to the problem.

Many authors use the term "personality disorder" interchangeably with "character disorder." In this book, the nosological designation of personality is used following the nomenclature in the *Diagnostic and Statistical Manual of the American Psychiatric Association*.

Personality Pattern Disturbances

The label "personality pattern disturbance" is applied to individuals whose life style demonstrates limited adaptive flexibility and certain relatively unchanging modes of expression and action. Individuals classified this way are characterized by unsuccessful but repetitive attempts to establish a stable, reciprocal relationship with the environment; seemingly rational but actually self-defeating attempts to gratify needs; and restricted, sometimes inappropriate, and often stereotyped thoughts and feelings in response to highly diverse situations.

Exhaustion of their limited repertory of problem-

solving techniques in the face of continued stress may be followed in these individuals by the employment of mechanisms originating in the earliest phases of development. These mechanisms, such as projection and denial, enable the individual partially to shut out current reality and to substitute need-gratifying and defensive fantasies in the form of delusions or hallucinations—in other words, these mechanisms may lead to psychotic behavior. Psychotic episodes of this sort are not, however, inevitable. When they do develop in the course of intensive psychotherapy or in response to other forms of interpersonal stress, they are usually temporary and circumscribed.

Personality pattern disturbances are frequently associated with neurotic symptoms and specific types of deviant behavior, such as sexual perversions. The following discussion deals, in some respects, in abstractions, as it focuses on certain aspects of behavior while ignoring others that are commonly coexistent.

Inadequate personality. This descriptive label is, in effect, a social value judgment. It reflects the lack of congruence between the standards of the evaluator and the behavior of the person being judged. The latter's day-to-day responses to emotional, intellectual, social, and physical demands regularly fall short of the expectations of others. He is usually referred for treatment by family members, agencies, or institutions that do not succeed in their own attempts to alter a life style that does not conform to their standards of effectiveness. In the patient's own view, however, his low level of performance seems natural and inevitable, although perhaps frustrating at times. He may find it difficult to understand the concern of others; more importantly, he may lack the motivation to amend his customary ways of thinking, acting, and feeling.

Clinical description. The inadequate personality may be described clinically as deficient in physical and emotional energy, socially inept, lacking in judgment, incapable of long range planning, and defective in task performance of all kinds. In an achievement-oriented culture, he lacks the necessary incentive to pursue even the minor successes that, under ordinary circumstances, could lead to the positive reinforcement of goal-directed behavior. His responses to the emotional, intellectual, cultural, and social demands of the group are relatively feeble. His social adjustment is borderline and he exists as a marginal member of society. Although he may hang on to a nondemanding job—he may, for instance, be the clerk who seems to have great difficulty in getting things right—he may also drift from one job to another with little concern for the future. Inadequate personalities attract little attention and frequently pass unnoticed, except under circumstances where their poor judgment results in disruption of established social mores or laws. Significant numbers of them are on welfare rolls and in such institutions as prisons and hospitals.

This diagnosis is made most frequently in the

lower socioeconomic strata. Sometimes it is used to label people with no education and poorly developed communicative abilities who might more appropriately be considered culturally disadvantaged or borderline mentally defective. Others, reacting to particular stresses with intense though shallow affective displays or impressing the observer with their emotional poverty and occasional stereotyped responses, may be labeled as simple schizophrenics. Still others may come to psychiatric attention through referrals from general medical clinics, which they may attend repeatedly, complaining of minor aches and pains.

Etiology. There are no satisfactory studies of the genesis of this clinical picture. In some instances the major factors appear to have been deprivational. In other patients, repetitive and seemingly incidental events during their developmental years may result in chronic fears or problems in impulse control—such as the control of reactive hostility—which are dealt with by inhibiting mechanisms so massive that their impact extends to all aspects of everyday life. In these instances the occasionally reported muting or damping of subjective experience is reminiscent of that described by patients suffering from chronic schizophrenic disorders.

Work and emotional inhibitions—an inability to achieve or feel deeply—may be accompanied by a persistent childlike need to obtain the relatively simple instinctual gratifications of the moment. The relatively conflictless need gratification, facilitated by a low emotional investment in interpersonal relationships and value systems, appears to have some value in protecting the individual against the possibility of a psychotic outbreak. Repeated tension discharges through rapid gratification of low intensity wishes help to maintain the stable state of the character organization; they mitigate, however, against an orderly development of those integrative ego functions that permit learning and accurate reality perception. Therefore, even in the absence of measurable physical or intellectual deficits, the inadequate personality functions maladaptively at a level below his native potential.

Treatment. The treatment of inadequate personalities has been discouraging. Their personal resources are limited, and they are frequently reluctant to make the effort to alter their life style. This is especially true when it has solved certain problems for them and brought them some secondary gain. Furthermore, the traditional one-to-one psychotherapeutic model activates anxiety, which is poorly tolerated and only tends to reinforce their need for premature tension release. Since learning is also impaired, any form of psychotherapeutic intervention becomes a formidable task.

Social class differences between patient and therapist also affect the outcome of treatment. But as more effective therapeutic techniques are developed for

lower class patients, these may prove useful in the treatment of inadequate personalities.

Schizoid personality. The person who is designated by this label is usually described in terms of a tendency to avoid close or prolonged relationships with other people. A corollary of this is a tendency to think autistically. Like others whose characterological features are so prominent that they warrant diagnostic tagging, he displays a limited range of responses to social cues; these, in turn, appear to reflect a limited repertory of ego-defensive and adaptive techniques. The cornerstone of the adaptive-defensive system in this instance is withdrawal, understood in both interpersonal and intrapsychic terms.

Etiology. The possibility that this primitive response is determined by genetic and constitutional as well as experiential factors has been considered by many observers. Individual differences in infants have long been recognized, particularly with reference to central nervous system activity. Infants demonstrate individual variations in base line motor activity as well as variations in response to identifiable stimuli. Infantile autism is perhaps the classical example of withdrawal as a response to early disturbed relationships.

Clinical description. Although withdrawal may begin as an adaptive mechanism, it hinders the process of socialization and the formation of relationships with others during the developmental years. Many adult schizophrenics have prepsychotic histories consistent with schizoid or, as they were called by August Hoch, "shut-in" personalities. It does not necessarily follow, however, that schizoid personalities must eventually become schizophrenic.

As children, schizoid personalities are frequently described as shy, docile, and obedient. Favorable parental comments regarding their model behavior and quietness further reinforce these ways of relating to others. They may exhibit marked sensitivity to signs of displeasure or rejection from those who are close to them. Since aggressive acts are rarely included in their repertory of usual responses, most threats, real or imagined, are dealt with by fantasied omnipotence or resignation. This is preferred to a resolution of the conflict by testing reality or by establishing the communication with others necessary for the expression of their needs. Maintaining an air of aloofness or emotional detachment may help the schizoid person soften the pain of isolation, but it transmits an impression of coldness and disinterest to others, still further increasing his alienation.

In childhood and adolescence, the schizoid character stands alone as an outsider looking in. He is frequently a noncompetitor, particularly in those activities requiring physical or emotional contact with contemporaries. His distinctiveness as a nongroup member may increase his self-consciousness and further isolate him from the group. In his isolation, he may invest his energies in nonhuman objects, and

with sufficient talent and persistence, such investment may provide an adaptably useful structure for his life. The boy chemist, the bookworm, and the boy astronomer are a few of the common reflections of creative focusing on the nonhuman.

Success in impersonal activities may facilitate healthier relationships with peers and group acceptance as their respect is gained. More often, though, these substitute activities enhance alienation by being labeled odd and result in increased self-consciousness and feelings of being misunderstood, frightened, and distrustful of others. The schizoid person may find solace in philosophy and align himself with political movements or world causes. As a fervent idealist or poet, he may be able to interact intellectually and invest genuine emotions in topics and issues, without running the risk of deep human intimacy or involvement.

It seems doubtful that mature sexuality can be attained in the presence of nonreciprocating relationships dating from early formative years. Seriously disturbed relationships within the family prevent the adequate resolution of developmental conflicts involving bodily needs and feelings toward parents necessary for progress toward sexual maturity. Many schizoid characters idealize love in an effort to stave off sexuality. In marriage, the sexual union may be intellectually compartmentalized as an obligation of the marital contract but divested of emotional involvement. Many such marriages are characterized by a virtual absence of meaningful communication. Misunderstandings or dissatisfactions remain unexpressed and, therefore, not adequately resolved.

Treatment. The treatment of schizoid personalities offers more promise than that of inadequate characters. There is frequently less social class difference in the therapist-patient dyad. The patient's tendencies toward introspection are more consistent with the therapist's expectations. Perhaps the restrictions imposed by the therapeutic setting on the degree of emotional involvement allow the patient an opportunity to identify with the doctor and use him as a model for future interpersonal relationships without the threat of being overwhelmed.

Cyclothymic personality. The cyclothymic's usual modes of thinking, feeling, and acting are descriptively opposite to those of the schizoid personality. He resembles the latter, however, in possessing a potential for psychosis if his usual defensive and adaptive techniques fail.

Clinical description. Unlike the schizoid, the person labeled cyclothymic is effervescent and outgoing, meeting interpersonal situations with friendliness and warmth and undertaking tasks with enthusiasm. He looks forward to challenges and is ready to compete with others. He often attracts many friends, who regard him as a fascinating though at times unpredictable individual. His life and theirs, however, may be

complicated by his moods of sadness, which sometimes alternate with periods of elation.

These alternating moods of cheerfulness and sadness differ from those of normal individuals in several respects. First, they are frequently stimulated by internal (endogenous) rather than external (exogenous) events, and they are cyclical in nature.

Second, their range and intensity exceed those found in normal individuals. Resembling a pendulum swinging in an ever increasing arc, the heights and depths of elation and depression may blend into a continuum ranging from normal to cyclothymic to manic-depressive.

Third, aberrant behavior may lead family members to seek professional help at a point when the cyclothymic personality no longer demonstrates good judgment and his reality becomes distorted. His enthusiasm may approach grandiosity, but he experiences great difficulty in recognizing the abnormality of his elation, and he rarely refers himself for treatment.

Sadness may develop slowly into a virtual paralysis of productive action. Or the depressive phase may approach cataclysmic proportions with such rapidity, with or without a clear cut precipitating event, that it may overwhelm and immobilize the cyclothymic character.

Etiology. The inclusion of cyclothymic individuals in the category of personality pattern disorders poses several questions. Certain data suggest a biological basis for regular mood fluctuations not clearly related to environmental circumstances. Whether, in these instances, elation reflects a defense against depression through the mechanism of denial under the control of biogenetic determinants is still open to question. A similar question may be raised about the possible mediation of depressive responses through ego-defensive mechanisms, such as the self-direction of hostility, under biogenetic control. Individuals who demonstrate a life style characterized by more or less constant deviations of mood from the social norms—that is, the depressive and hypomanic characters—may be discussed in the same frame of reference as the cyclothymic character.

Histrionic personality. The substitution in 1952 of the terms “conversion reaction” and “dissociative reaction” for “hysteria” in the *Diagnostic and Statistical Manual* precluded further formal recognition of a clinically accepted though poorly described syndrome, the hysterical personality. The literature of preceding years was confused by usage—“hysteria” as described by Charcot and Freud, “hysterical personality” as a nonpsychiatric medical label covering a wide range of problems from malingering to psychophysiological visceral disorders, “hysterical” as used in a defamatory sense by the laity. A semantic solution may be achieved by using the term “histrionic personality” to designate those individuals described as hysterical personalities by Chodoff and Lyons.

Clinical description. The people described in this manner are vain, egocentric individuals displaying labile and excitable but shallow affectivity. Their dramatic, attention-seeking, and histrionic behavior may encompass lying and pseudologia phantastica. They are conscious of sex and appear provocative, but they may be frigid and are dependently demanding in interpersonal situations. They have a life-long history of seriously disturbed relationships with others. The loss of a parent through divorce, desertion, or death is often reported.

Histrionic personalities under stress may exhibit impaired reality testing, intensive fantasy production, and convictions about the motives of others bordering on delusion. In moments of repose, they are characteristically vague and imprecise about emotionally significant matters. They cannot express their inner feelings with accuracy and often utilize bodily action for communicative purposes.

Although histrionic personalities may exhibit conversion reactions, the latter can occur in association with almost any type of character structure. Histrionic character features occur more frequently in Western society among women. They are, indeed, considered feminine by our societal standards, and male histrionic characters are frequently described in this way.

Etiology. Marmor stated that the pre-oedipal period is characterized by intense frustration of oral receptive needs as a consequence of early parental defection or desertion or, on the other hand, by excessive gratification by one or both parents. As children, histrionic personalities may be thumb suckers, and they may feel unloved and lonely. Attempts to please others may include coquettish mannerisms, coyness, or seductiveness. Attention may also be gained through temper tantrums, the dramatization of illness, or the exaggeration of feelings. Overeating and obesity are doubly valuable, producing both the temporary satisfaction of primary needs and the secondary gain of parental concern. Each minor success reinforces an essentially nonverbal, somatic style of communication and immature, clinging ways of relating to others.

The impact of such early experience is considered basic to their insatiable needs for love and affection in adult life. According to this theory, fixation at the oral level of development prevents the ultimate attainment of genital sexuality, and these individuals continue to translate all interaction into terms of unmet oral needs.

These infantile needs inevitably result in frequent disappointment in adult relationships, particularly in the sexual sphere. The provocative and seductive behavior of women, for example, elicits adult sexual responses from their male companions, which may be perceived as frightening or disgusting, since their basic wishes are for nonsexual, protective love. Prominent symptomatic consequences of this situation are fri-

gidity and promiscuity, the latter representing the constant search for a type of love that can never be found.

The close association of histrionic personality manifestations with schizophrenic illness has been noted by many observers, in terms of both early developmental history and symptomatology. The deprivation suffered in infancy is considered similar to but lesser in degree than that preceding infantile autism.

Treatment. The treatment of histrionic personalities can be difficult, lengthy, and frustrating. As love and affection are given priority over understanding and insight, the therapist's interpretations are often viewed as rejection and thus promote renewed attempts to gain his affection. If the stress of therapy is greater than can be tolerated by a poorly integrated ego, psychotic decompensation may result. Seemingly early positive results in psychotherapy should alert the therapist to the possibility that his patient is complying in order to please him, rather than really working out her problems.

An additional obstacle to successful psychotherapy is the histrionic personality's restricted communicative ability. Vagueness, superficiality, and a lack of awareness of inner feelings, other than the recognition of wanting love, leave the therapist little choice but to rely on the patient's observable behavior. Since the patient has difficulty understanding the meaning or intent of her own somatic language, her perception of her bodily changes only tends to confuse and magnify her feelings of not being understood.

Paranoid personality. People designated by this label share many of the traits found in schizoid personalities. They are further distinguished by their defensive position against the world and the regular use of projection as a way of dealing with unacceptable inner feelings and of fending off others. The paranoid personality is uniquely sensitive to real and imagined cues, particularly of a sexual or hostile nature, and quick to translate them into personalized references. His defensive tactics include an aggressive and suspicious attitude toward others as potential enemies. Although he gains a sense of importance in being the focal point of the transgressions by others, his fantasied elaboration of their possible reasons for attacking him tend to further jeopardize his sense of self-adequacy and a secure self-image.

Etiology. Clinical studies of paranoid characters frequently reveal an opposite sex parent who is domineering, overprotective, and ambivalent and a same sex parent who is submissive, passive, and relatively unavailable to the child as a suitable model or object for identification. Similar unavailability may follow when the parent of the same sex instills feelings of inadequacy through intimidation, hostility, and rigid controls. Both sets of circumstances interfere with the development of a stable self-image and gender role and of clear ego boundaries. The child may be faced with an almost insoluble problem in defining

his identity separately from that of the overwhelming parent.

The frustration and anger felt by a child in his affective relationships during the early developmental years reinforce feelings of rejection and suspiciousness of the motives of others. Aggressive and hostile feelings toward the feared and rejecting parent may be repressed, but the battle can continue with siblings, later with peers, and then with the world at large. Two self-defeating alternatives are present: one may comply and surrender to the omnipotent parent figure, leading later to a homosexual pattern; or one may resist and rebel defensively, leading to a regressive disorganization of ego functions, specifically hypervigilance and ideas of reference.

Clinical description. Much of what the paranoid personality undertakes is designed to prove his superior worth. Although he may be highly efficient, he lacks the flexibility needed for innovations, and he reacts sullenly to suggestions or criticisms. To achieve his goal, he may belittle and criticize the efforts of others. Humor and relaxation are incompatible with reaching this unattainable but highly desired goal of worthiness and, therefore, become subordinate to conscientiousness and striving.

Since he is insecure, the paranoid personality may never achieve feelings of adequacy or be comfortable with his self-image. He must remain constantly alert to people or situations that threaten the identity to which he aspires, and he often attacks in order to avoid being attacked. His very actions bring about that which he tries to avoid: further rejection and damage to his self-esteem. Any rejection is viewed as further evidence of a hostile world, and the partial truths expressed about him by those who are rejecting or, more usually, indifferent reinforce his suspiciousness. The paranoid personality may eventually become litigious in his self-righteousness, champion causes that further his feelings of exaltedness, and gradually lose contact with reality.

The association of homosexuality and paranoid behavior was recognized by Freud and has been elaborated on by others. Among paranoid personalities, a homosexual episode or the threat of homosexuality may herald an acute decompensatory episode.

Treatment. The psychotherapeutic treatment of paranoid personality disorders must be undertaken with the following considerations in mind. These individuals fear and simultaneously desire close meaningful relationships with others but seem unable to admit and accept these affective needs. Novey stated that, operationally, paranoid personalities suffer from a quantitative distortion of their perceptual experiences, which makes them poor reporters of actual events. For this reason, therapeutic emphasis is laid on the patient's inner experiences and reactions to events in relation to his immediate interaction with the psychiatrist.

Personality Trait Disturbances

This category includes those individuals whose behavior is organized around a single, well crystallized response tendency. Such a tendency represents the residues of unresolved developmental conflicts as they have contributed to adaptive efforts that, although possibly useful in early periods of life, persist into adulthood as useless or self-destructive responses.

The separation of personality pattern from personality trait disturbances in the current psychiatric nomenclature is not completely satisfactory. The latter, however, seem less pervasive in their influence on total personality structure. They are, furthermore, less readily identifiable as socially or psychiatrically significant, except in retrospect after a characterological decompensation brings them to the attention of physicians or other agents of social control.

Compulsive personality

Clinical description. This diagnostic label is applied to individuals whose actions are driven by needs for perfection and orderliness, who cannot tolerate ambiguity, who seem unable to change their minds after having arrived at decisions, and who have a need for closure and task completion that may not be appropriate to the context in which they are working or to the job at hand. An obligatory quality pervades much of their life experience.

A moderate degree of compulsiveness often seems desirable by Western standards and may be necessary for certain types of professional achievement. Even one whose compulsiveness warrants the diagnosis of personality disorder may successfully engage in occupations suited to his temperament. These involve repetitive tasks, requiring concentration on details in a highly structured situation. Such an adjustment is brittle, however, to the degree that it depends on a stable social context.

When forced to work under circumstances over which he has no control and which may vary unpredictably, the compulsive personality may become anxious and disorganized. If his working situation depends on the moods or the changing directives of a supervisor, he may become resentful, stubbornly resistive to change, and suspicious of the motives of those in positions of power. If under the stress of unanticipated deadlines so that he cannot perform with his usual ruminative thoroughness, he may react with helplessness. If passed over for advancement, his envy, resentment, and frustration at the good fortune of another may reach obsessive proportions.

If, on the other hand, he is promoted, he may become disturbed when delegating tasks to others who do not demonstrate a degree of thoroughness equivalent to his own. As a supervisor, he is one who breathes down the necks of his subordinates and drives them to distraction by his attention to petty detail and his insistence on following the letter of the law. His need

for perfection and order always carries with it the potential for conflict with others who may view him as obstructionistic, petty, inordinately scrupulous, and irascible.

Compulsive personalities commonly avoid or delay marriage because of their precise expectations regarding a suitable mate and their obsessive doubts about making a decision of major significance. Marriage to someone with like characteristics results in a formalized, emotionally distant living arrangement. Or a passively compliant, dependent person may be attracted to the compulsive character, who appears on the surface as strong and self-reliant. In the latter instance, a type of symbiotic relationship may persist for a time. However, the compulsive personality is always able to find fault. By imposing his standards on his spouse, he increases the emotional distance between them, destroys her security, and, thus, experiences an intensification of his own sense of alienation.

Such marriages may be characterized by a failure in full genital sexual consummation. This is particularly true in the presence of the anal interests that appear to be invested with a persisting significance of almost erotic quality in many compulsive personalities. Preoccupation with the regularity and consistency of bowel movements (as well as with the corresponding details of dietary intake) and of smells and sounds related to excretory functions may provide a source of gratification more meaningful to the patient than mature sexuality. This persisting interest is not confined exclusively to the bodily functions and apertures concerned with oral intake and sphincter control; it may be focused on other activities and areas related to maintaining physical integrity and cleanliness, such as exercise, sleep, skin care, and dental hygiene. In short, this pattern of obligatory attention, rigidly applied to minutiae, control of which is essential for the maintenance of a high degree of order and predictability, implies a narcissism that can preclude the development of sustained, warm human relationships free of nagging doubts, suspicions, and irritations.

Etiology. The social transmission of patterns of characteristic behavior inevitably involves the parents (or their surrogates) of patients to be. Parents of compulsive personalities have frequently been described as hard working but inflexible, with little time or energy left for the problems of sustaining a loving, supporting, and giving relationship with children and adolescents whose behavior fluctuates and whose needs make it impossible for them to conform completely to a rigidly controlled life situation. Such parents may offer their children conditional love—that is, dependent upon conformity to their expectations—or punitive behavioral controls under the guise of love.

The young child trapped in this context may attempt to withdraw, to revive or maintain behavior patterns that offered solace at earlier stages of development, or to express his frustration through

temper tantrums. The shape of his eventual compliance reflects the degree of trust or fear learned through past experiences, the nature and intensity of particular stresses to which he is subject, and his physical and emotional maturity and competence at the times the stresses occur. Such compliance, which is both adaptive and defensive, is reflected in the scrupulousness, fastidiousness, obedience, and punctuality of the "good child," who may occasionally display unexpected flashes of cruelty or uncontrolled temper outbursts.

The utilization of rigidly maintained defenses, such as reaction formation and isolation, against tendencies to soil, harm, or destroy is also reflected in consistent and inappropriate smiling or submitting responses. That is, the fixed, relatively unvarying message of good humor and meekness that is transmitted to others reflects the tight control under which potentially hostile tendencies must be contained. Just as often, the resolution of the rebelling-conforming conflict appears in such derivative characteristics of warded off hostility as stubbornness, avarice, possessiveness, and arrogance or pretentiousness.

The early history of this development is thought to lie in the period between the ages of 9 months and 2 years. This period, when the child begins to develop control over his sphincters, usually sees the initiation of parent-child struggles over toilet training, bedtime hours, and the control of hostile expression. Some anally focused parents actually assume control of the child's sphincters themselves through the repeated use of rectal enemas or dilators. Early problems involving parental regulation of eating behavior assume new intensity as they are linked to toilet behavior. The increasingly rapid development of speech at this time, permitting a wider range of hostile and complaint communication, also contributes to new levels of complexity in the child's developing system of internal and external control.

A number of related factors may be involved in the genesis of the compulsive personality. Weaning may overlap the toilet training. The arrival of an additional sibling means magnified deprivation. The child's claims for a reciprocal affective relationship with his parents may reinforce their needs for control and increased emotional distance in curbing his spontaneity.

This stage of life, during which the child achieves mastery over the excretory sphincters and to some degree over the oral functions of talking and ingesting, was described by Freud and Abraham as the anal period. Freud described the nature of coprophilia and pointed out that, following repression, such interests can be sublimated into artistic pleasures or, through reaction formation, develop into a special love for cleanliness.

Abraham emphasized the impact of early traumatic experience on infantile narcissism. Success requires that the child accomplish tasks for the sake of the

parent and is dependent on his ability to transfer to people those feelings that were previously narcissistically bound. Premature demands for cleanliness produce fear and anger, impairing the child's developing capacity to love. A need to resist external controls (obstinacy), preoccupation with details, orderliness, perfectionism, meticulousness, envy, unproductiveness, interest in money, parsimony, sadistic tendencies, and anal erotism—all attributed to unresolved conflicts during this phase of development—were designated by Freud as comprising the anal character.

Most compulsive characters do not come to psychiatric attention, although they may be diagnosed by their acquaintances as stingy, stiff, rigid, conscientious, religious, or hard working. The psychiatric label implies that their characteristic behavior has become so intense as to pervade every aspect of daily life in a manner that interferes with effective adaptation and pleasure. The step from this point to that of the compulsive neurotic reaction with clearly symptomatic rituals, interference with which results in intense anxiety, may at times be a small one.

The defense system reflected in compulsive behavior is vulnerable to disorganization, which can result in other clinical syndromes. Effective utilization of repression and reaction formation to gain mastery over destructive impulses, for example, may require the exercise of an unusual degree of vigilance regarding threats from within and without. Thus, unusual sensitivity to the possible hostile motives of others may permit the compulsive personality to withdraw from contact with them or defend himself in other ways against the possible activation of potentially uncontrollable rage.

The continuing need to deal with poorly resolved internal conflicts may contribute to feelings of tension and fatigue and may lead to the utilization of other defense systems reflected in obsessive-compulsive neurotic reactions, neurotic or psychotic depressions, or paranoid-schizophrenic states.

Those compulsive personalities who do become psychotic usually do not decompensate until later years. Decompensation is often precipitated by factors related to employment, including retirement or transfer to another location. Awareness of advancing age, with the loss of status and physical or mental powers, the death of a spouse, or the loss of children through marriage may be followed by depressive illnesses of neurotic or psychotic proportions or by paranoid psychoses.

The earliest changes preceding a psychotic reaction may be those reflecting a transition from the stage of a compulsive personality to that of a compulsive neurosis. At this point, the polarity of compulsive features is seen in the combination of defense and the disguised expression of what has been warded off. Such combinations regularly include extreme cleanliness coexisting with filthiness ("Scratch a compulsive, and you will find dirty underwear"); extreme, petty penurious-

ness, resulting in gross waste; and frantic efforts at efficiency, resulting in virtual paralysis.

The late stage of decompensation, where a severe and socially incapacitating neurosis cannot easily be differentiated from psychotic behavior, may be illustrated by the case of a woman with an obsessive fear of contamination by dirt and germs on the floor. After years of progressively restricting her behavior, she finally confined herself to bed, where, while avoiding the dirt of the floors and streets, she soiled herself with her own feces.

Some patients who present the syndrome of a compulsive personality on first encounter prove, after more thorough investigation, to have acute schizophrenic reactions. In some of these instances, the apparent characterological picture may be understood as reflecting efforts at restitution or recovery from the psychotic disorganization rather than as a reinstatement of a previously existing personality pattern. A narrowed range of repetitive activities can be protective, allowing progressive attempts at conflict resolution and providing sufficient stability for the patient to rebuild his bridges to reality. The isolation, rigidity, adherence to routine, attention to small details, and intolerance of ambiguity and change displayed by many recovered schizophrenics are descriptive elements of the compulsive personality.

Treatment. The psychotherapy of the compulsive personality presents all the classic problems involved in the treatment of any personality disorder and some special ones. In the first place, it is misleading even to speak of treating such a disorder because, when the person described in this way does consult a psychiatrist, he does not usually come on characterological grounds as such. Like the other personality disorders, the subjective experience of the compulsive is ego-syntonic. The affected individual does not conceive of himself as ill or deviant. Unlike many others, however, he is not apt to be brought to treatment by the suffering community, since his behavior is often socially useful and, broadly speaking, reality-syntonic. Thus, when he presents himself in a doctor's office, it is because he is suffering the consequences of a breakdown in the defensive and adaptive system reflected in his characterological picture.

This breakdown can result in depressive, schizophrenic, or obsessive-compulsive symptoms. In each instance, the patient may suffer from a variety of ego-alien symptoms. Or his attention may be focused on some aspect of his bodily structure or function, so that he consults a general physician and never reaches a psychiatrist. In this case, the major therapeutic effect will be that exerted through the establishment of a chronic, dependent relationship with the physician, reinforced by the placebo effect of whatever drugs are administered and the occasional guilt-expiating punishment or direct masochistic gratification imposed by unpleasant diagnostic or unnecessary therapeutic procedures. Progressive behavioral de-

terioration may be stopped in this way and a marginal status quo maintained.

In the event that the person becomes a psychiatric patient, the therapist has to choose between a treatment regimen based on anxiety- or depression-alleviating drugs combined with supportive psychotherapy on one hand, and, on the other hand, a treatment regimen that is exploratory, uncovering, and essentially reconstructive. The choice is made, as usual, on the basis of the patient's capacity to tolerate the stress of psychological exploration and a potentially turbulent transference relationship, his capacity to introspect, his motivation to collaborate in a long term treatment plan, and his education and socioeconomic status.

If the physician chooses drugs and supportive psychotherapy, it is quite possible that rewarding life experiences, accomplished with the doctor's active support and clarifying discussions, may permit the learning of new social and personal techniques of anxiety reduction and need gratification and the abandonment of old ones, so that the patient may be reconstituted as a compulsive but functioning personality.

If more intensive psychotherapy is chosen, two considerations may be emphasized. First the hazards of transitory psychotic episodes in the course of intensive therapy or psychoanalysis are, perhaps, greater with the compulsive personality—who has, after all, begun to decompensate before consulting the therapist—than with the other personality disorders.

The second consideration is more appropriate to the case of the obsessive-compulsive neuroses, but it is mentioned because the compulsive personality who comes for treatment may be one who has begun to display classical symptoms of decompensation after years of rigidly controlled behavior. The treatment of choice for obsessive-compulsive neurotics, following the early experiences of Freud and his followers, has been psychoanalysis. The accumulated experience of many analysts suggests, however, that the analytic ritual may be mainly effective in many instances as a substitute neurosis, offering no protection against the recurrence of disabling symptoms when the relationship with the analyst is severed. For some patients with long standing obsessive-compulsive symptoms, a flexible, nonritualistic type of psychotherapy may be useful—one in which appointments are made at irregular intervals, ruminative free associations are actively discouraged, and major emphasis is placed on the immediate therapeutic transactions and life situations, with a deliberate deemphasis of the exploration of developmental events. Such a procedure over a period of several months, with specific tactics based on psychoanalytic insights into the current therapeutic relationship, has appeared to hold some promise.

Emotionally unstable personality. This label is applied to the individual who repeatedly exhibits

volatile affective and related behavioral responses in the face of minor stresses. Such a person has a low response threshold for emotionally meaningful stimuli. His tendency to rapid response with little modification through learning increases the probability of progressive perceptual distortion, poor judgment, and inappropriate behavior. Immediate cognitive functioning can be disorganized by affective outbursts.

Etiology. Emotionally unstable behavior has been viewed as a function of sociocultural and developmental factors and of neurophysiological immaturity.

Clinical description. In the absence of stress, the emotionally unstable personality may be affable and enthusiastic and appear relatively well adjusted. When confronted with seemingly insignificant events or clear disappointments, however, he may react explosively, sometimes to the point of temper tantrums, physical assaults, or suicide. These actions may be considered, in part, as attempts at nonverbal communication and reflections of loss of control. They may be compared to uncontrolled infantile rage reactions, both in terms of their immediacy and of the person's total involvement.

The emotionally unstable personality tends to form shallow relationships with others, viewing them as serving his own immediate needs. Petty jealousies and arguments interspersed by periods of carefree unconcern for adult responsibilities are usual.

The emotionally unstable personality is usually known to his family and those around him as "nervous," "easily upset," or even, in the folk sense of the word, "hysterical" rather than sick.

A psychiatric diagnosis may be made as an aid to disposition if the patient is a member of an institutional community, such as the military or a school. In such a setting, his behavior may provoke anxiety and hostility in others, and his usefulness to the group may be minimal. His evanescent and unpredictable turbulent emotional displays often prevent rational problem solutions by those around him. In desperation, they may request hospitalization or arrest or retreat into a state of helpless resignation until his current emotional storm has passed. Occasionally, anxiety triggered by a physical complaint will bring him to the notice of a general physician, who will then make the referral to a psychiatrist.

Differential diagnosis. The instability sometimes associated with early multiple sclerosis, Huntington's chorea, and other organic brain disorders has been compared with that encountered in emotionally unstable personalities. Neuroanatomical behavioral correlates with lesions in the hypothalamic area are well established. Sham rages produced in cats by severing posterior hypothalamic cortical connections resemble the erratic behavior accompanying tumors in the floor of the third ventricle that impinge on the posterior hypothalamus. The inappropriate euphoria in multiple sclerosis and behavioral modifications in cases of encephalitis are attributed to lesions in the

same area. Similarly, basal ganglia motor disorders may be preceded by changes in affect and impulse control resembling the emotionally unstable personality. Whether instability is thought to reflect character defects in biogenetic, sociocultural, or psychological terms must await development of more sophisticated investigative techniques than now exist.

Treatment. Treatment of an emotionally unstable personality carries a poor prognosis. Insight into the maladaptiveness of his own behavior is rare or short-lived and then only experienced in the immediacy of these self-created crises. More commonly, he tends to rationalize his behavior, to deny its pathological quality, and to resist efforts at intervention. These factors, his inability to form prolonged close interpersonal relationships and to tolerate anxiety, and his tendency toward emotional acting out of his conflicts all impair efforts at treatment.

Hospitalization can be used to impose external controls during acute episodes. This may permit the establishment of a therapeutic relationship in which the doctor, as a parental figure and a representative of a social organization, may function as an auxiliary ego for the patient. Ultimately, the protection afforded in this way may allow a degree of delayed maturation. Similarly, the general physician, by the judicious use of anxiety-alleviating drugs, advice, and opportunities for ventilation may shepherd the patient through repeated crises and gradually become an important source of security for him. Whether or not the physician should look forward to psychological exploration with the aim of eventually weaning the patient from the dependent relationship is questionable. It is possible, however, that similar therapeutically significant bonds may be formed to task-oriented groups. Such devices as therapeutic social clubs and sheltered workshops may be useful in this respect.

Passive-aggressive personality. This grouping includes three subclassifications: (1) the passive-dependent, (2) the passive-aggressive, and (3) the aggressive. Its establishment as a general diagnostic category is based on a theory of the etiological importance of the highly dependent period of infancy during which sucking and related activities involving the mouth and perioral areas have been attributed special importance. For some infants, sucking may be unsatisfactory because it does not provide adequate nourishment or because of defective neuromuscular mechanisms. In others, it may produce unpleasant satiation or be associated with forced contact with the smothering or choking breast. Still other difficulties may stem from the general nature of the infant's contacts or lack of contact with the mother during feeding by breast or bottle.

Biting during this phase has been interpreted as a direct consequence of frustration associated with weaning or the failure to obtain a variety of dependent gratifications. Such frustration has also been regarded by some as resulting in a displacement of pleasure-

seeking activities and sensations to other body areas, such as the anus.

The subtypes of the passive-aggressive personality can be viewed in terms of the variable experience suffered during this period of complete dependence, when the major relationships with others appear to be mediated through being fed. Presumably overindulged during infancy, the passive-dependent individual, lacking responsible participation and involvement with others on a mature level, continues to think, act, and feel that his dependent needs will be magically gratified. The passive-aggressive individual manifests characteristics that, according to Freudian theory, are associated with both the oral and anal character structures; these include procrastination and stubbornness associated with intense cravings for acceptance, generosity, and verbal demands for attention. The genesis of the aggressive character type has been traced by some psychoanalysts to the oral biting phase associated with early dentition and characterized by an ambivalence generally not present in the dependent and passive-aggressive types. His envy, hostility, and jealousy are thought to be derivatives of unresolved conflicts in this phase.

Passive-dependent type. This individual relates to others by pleading helplessness; he seems incapable of decisive action, even with strong support. The rewards of dependency, including attention and love, reinforce his clinging responses. Dependent behavior also offers a disguised means of controlling others. Such manipulation may be illustrated by the person who has never learned to drive an automobile or assume the initiative in shopping for food. Under such circumstances, protestations that one would be willing to act if his condition would permit are common.

Cultural expectations reinforce dependent behavior in women during late adolescence and early adult life. Passively dependent females may fulfill a need for certain men who come to their rescue or need to possess them. The social role of the beautiful but helpless woman, the property of a dominant male, can aid her in maintaining a tenuous and superficial relationship with others. This congruence of social role and personality usually precludes the diagnosis of a disorder until such time as diminishing physical attractiveness or other changes result in rejection and loneliness. At this point, the primary complaint is apt to be depressive, hypochondriacal, or somatic in nature.

For males who are passive-dependent, one symbolic mother is substituted for another in a repetitive fashion. Many seem incapable of employment except under protected circumstances and with constant support. The diagnosis of a passive-dependent personality disorder may be made more readily in men than in women, since there is no culturally acceptable male social role of this type. This personality resembles the psychoanalytic oral personality.

Passive-aggressive type. The person labeled in

this way characteristically expresses hostile or destructive wishes through covert and passive means. A major function of such behavior is to achieve the oral-dependent needs never met in the family. He may be relatively compliant and passive in his daily relationships. When faced with situations that threaten to terminate his dependency on others, pouting, stubbornness, and procrastination become evident.

In work settings, he may passively and publicly accede to conditions he finds unacceptable while covertly undermining the situation by complaining bitterly to others, procrastinating, and performing inefficiently. Passive obstructionism and failure to contribute productively to group tasks are characteristic. His unresolved narcissism prevents his giving up his self-interest in favor of interest in others.

A major hazard in the treatment of the passive-aggressive personality is a tendency to develop a prolonged ambivalently dependent relationship with the psychiatrist. Subtle resistances are likely to be masked under a facade of conformity to the therapeutic ritual. The therapist is frequently blamed for changes in the patient's life situation, identified by the patient as inimical and a consequence of therapy. In the face of occasional overt acting out behavior, realistic limit setting may become necessary.

Aggressive type. Sulking and tantrum-like behavior in the face of frustration is reminiscent at times of the rebellion of children. At other times, aggressively attention-demanding and openly critical and belittling behavior are present. The aggressive character can be argumentative, contrary, and authoritative, involving people in prolonged discussions and attempting to make them feel defensive. This is particularly true in his relationships with authority figures, which may be tinged with unreasonable suspiciousness of their motives and complicated by litigious acts. His attempt to intimidate others can be understood as a means of increasing his precarious feelings of self-esteem. These attempts may take the form of overtly loud, bumptious, or dominating behavior. Caustic verbal aggressiveness, in these instances provocative and unrelenting, has been considered a by-product of persisting oral-sadistic drives stemming from earlier developmental struggles.

Psychoanalytic investigation may reveal feelings of omnipotence and dependency needs, which are dealt with by reaction formation. They may be reflected in more subtle but equally ruthless pursuit of private ambitions at the expense of others. Or they may be reflected in clearly antisocial, episodically destructive behavior. When, in these latter instances, a full or partial amnesia occurs for much of the episode, the possibility of a temporal lobe dysrhythmia should be suspected.

Other personality trait disturbances. Certain ways of behaving that suggest the label of personality trait disturbance depend for their identification on current sociocultural standards. Such

socially stereotyped figures in the 20th century Western world include comics, beatniks, eggheads, racists, do-gooders, and others. In many instances, the social stereotype represents a caricature based on an easily observed quality of behavior, such as the back-slapping politician who presents himself as an accepting, giving, "hail fellow well met" who is, nonetheless, immediately recognized by his admiring supporters as clever, observing, even devious in the service of his goals, which coincide importantly with their own.

The "as if" personality. Among the specific personality types that have been psychologically described, the personality described by Helene Deutsch has attracted much attention. The "as if" personality has a defective capacity for love and assumes pseudoaffective relationships through identification with others. He represents a behavioral adaptation to external reality through the mimicry of others without appreciation for their real emotions.

Such behavior is thought to reflect a defective ability to invest emotional interest in others due to deprivation during the period of most intense early dependency. Strong persisting needs for love and a precarious self-esteem contribute to a tendency to develop narcissistic relationships with others—that is, to relate to people who are similar in important respects. One consequence of a defective capacity to establish long term loving relationships with others can be impaired superego development.

Although the "as if" personality may appear normal in his day-to-day relationships, his chameleon-like tendencies emerge in an unusual ability to copy and imitate without originality. Interpersonal relationships appear on the surface to be appropriately intense. The display of friendship, love, or sympathy, however, is made without warmth. This lack of emotional commitment in the presence of seemingly appropriate behavioral response may cause others to sense that something is absent.

The response of others to this imitative behavioral mode makes the "as if" personality sensitive to environmental cues. Relationships with others are usually short-lived, requiring replacement in a repetitive fashion. Identification permits a transitory incorporation of the morals of others, regardless of their intrinsic quality. Antisocial behavior, possible under these circumstances, may be replaced as quickly by contradictory values with a succeeding identification. The lack of a true identity further hampers the discrimination of self from external reality and may, under stress, lead to psychotic behavior. In this case, identification is no longer limited to human beings but extends to inanimate objects, concepts, or symbols.

The grotesque-comic personality. As described by Annie Reich, this personality type reveals certain developmental deficiencies. Unlike successful comedians, such a person lacks the talent to creatively de-

sexualize feelings in an acceptable manner, perceived by others as comic witticism. The grotesque-comic fails to achieve full sublimation of conflicting sexual feelings and is unable to neutralize aggressive wishes. This is experienced as emerging anxiety, which further threatens to damage self-esteem and evokes feelings of impotence and helplessness. The individual reenacts repetitiously in caricature an unsuccessful attempt at mastery of past anxiety. Such reenactment contains elements of exhibitionism, aggression, self-humiliation, and self-punishment. Some describe this behavior as resembling a repetition compulsion coupled with laughter.

The grotesque-comic uses his body to ridicule his innermost fears and wishes and simultaneously discharges his hostility and frustration toward the audience. In effect, he is able to seduce through laughter the historically sought object (a parent) who rejected him during his formative years.

As the ego evokes these instinctual wishes for the purpose of eliciting pleasure, anxiety may not be felt unless the person fails to elicit laughter. This failure may be due to the quality of the presentation, the lack of receptivity of the audience, or the audience's boredom, apathy, or disgust. What began as humorous caricature is now acutely experienced as a confrontation with reality, and the individual feels exposed, humiliated, and rejected. The audience on whom the grotesque-comic depends assumes the function of an external superego and requires repeated comic reenactment to reinforce feelings of acceptance and approval.

In failing to utilize sublimation successfully, grotesque-comics are frequently prone to depressive episodes. Even in the presence of a receptive audience, the original injury sustained from the rejecting parent cannot be erased and requires constant testing for assurance.

Suggested Cross References

In addition to the pathological types of personality discussed in this section, other characterological types described by Freud are assumed to derive from various stages of psychosexual development. A description of the oral, anal, and genital character types may be found in the chapter on classical psychoanalysis (Chapter 6) in Area C, on current theories of personality and psychopathology. That chapter also gives further information regarding the development of personality and psychopathology from the viewpoint of the psychoanalytic model. Also in Area C are sections dealing with various alternate theoretical approaches. More detailed information regarding the treatment modalities mentioned in this section may be found in Area G, on psychiatric treatment. Problems regarding the treatment of the poor, which was referred to in reference to the therapy of the inadequate personality, is discussed by Brotman in Section 46.4 in Area I, on community and social psychiatry.

Cultural and social determinants of personality and psychopathology are discussed in Wallace's section on anthropology (Section 4.1) and in Silverman's section on sociology (Section 4.2) in Area B, on the basic behavioral sciences.

Chapter 26

Personality Disorders. II: Sociopathic Type: Antisocial Disorders and Sexual Deviations

26.1 ANTISOCIAL AND DYSSOCIAL PERSONALITY DISORDERS

ELI ROBINS, M.D.

In the American Psychiatric Association's *Diagnostic and Statistical Manual*, the term *sociopathic personality disturbance* is used to include the following diagnostic terms: antisocial reaction, dyssocial reaction, sexual deviation, and addiction as a primary diagnosis. This section discusses only *antisocial reaction* because the other diagnoses are treated in other sections and because the concept and description of dyssocial reaction is in such an unsatisfactory state.

Antisocial reaction is defined in the *Diagnostic and Statistical Manual* as follows:

chronically antisocial individuals who are always in trouble, profiting neither from experience nor punishment, and maintaining no real loyalties to any person, group, or code. They are frequently callous and hedonistic, showing marked emotional immaturity, with lack of sense of responsibility, lack of judgment, and an ability to rationalize their behavior so that it appears warranted, reasonable, and justified.

On the other hand, however, dyssocial reaction is defined in the *Diagnostic and Statistical Manual* as follows:

This term applies to individuals who manifest disregard for the usual social codes, and often come in conflict with them, as the result of having lived all their lives in an abnormal moral environment. They may be capable of strong loyalties. These individuals typically do not show significant personality deviations other than those implied by adherence to the values or code of their own predatory, criminal, or other social group. The term includes such diagnoses as 'pseudosocial personality' and 'psychopathic personality with asocial and amoral trends'.

In the author's opinion, dyssocial reaction either does not refer to a psychiatric illness or has not been studied in a manner to differentiate it clearly from antisocial reaction. However, the contrast between dyssocial reaction as above defined and antisocial

reaction as discussed in this chapter will become evident from the data presented in this chapter. The term "dyssocial reaction," although a logically and psychologically impeccable concept, appears to be so rare that it may be safely assumed that the overwhelming majority of criminals would fit into the diagnostic category of sociopathic antisocial personality, and not dyssocial reaction.

The acute question confronting psychiatry with regard to the classification of antisocial reaction is the establishment of valid common denominators to define this syndrome in such fashion as to clear away the many confusing philosophical, moral, and clinical issues that have grown up about it during the 130 years since its description by Prichard. Even Prichard's original description of "moral insanity" contained many different entities. In the succeeding years, attempts have been made to describe this condition more precisely. Contrasting with this tendency has been one to extend the limits of its description, making it less precise and more difficult to deal with as a substantive scientific issue. Resulting at least in part from this latter tendency, the use of the term *psychopathic personality* (another of the many names by which this syndrome has been known) became a psychiatric wastebasket for a heterogeneous collection of illnesses with etiologies which were not known and with clinical pictures which differed in essential elements. These ambiguities were to some extent taken cognizance of in the *Diagnostic and Statistical Manual* of 1952 by separating off two groups of disorders, personality pattern disturbance and personality trait disturbance, and by the coining of two diagnostic terms to describe primarily antisocial disorders: antisocial reaction and dyssocial reaction.

The attempt to give a clear description of an illness with unknown etiology, pathogenesis, and total clinical manifestations suggests that mild and atypical cases may well not be included, or at least their significance will not be properly evaluated. Despite these shortcomings, a description of antisocial reaction, with regard to its clinical picture and natural history is

important for its clinical usefulness, for the establishment of a homogeneous group, for research into its etiology and pathogenesis, and for the tentative delineation of the mild cases and atypical cases.

To generalize, studies of antisocial reaction have suffered from the lack of detailed systematic clinical description and from insufficiently detailed and prolonged follow-up. These lacks have recently been remedied in a series of studies of L. N. Robins, P. O'Neal, and associates (Robins, 1966); Guze et al.; and Ehrlich and Keough. L. N. Robins' monograph contains a detailed description of the methods and results of a study based on a 30-year follow-up study of 524 child guidance clinic patients and 100 controls. As adults, 94 of the patients received the diagnosis of antisocial reaction. Guze's investigation was based on the study of 223 felons. Ehrlich and Keough's investigation was based on the study of 50 patients with the diagnosis of antisocial reaction in a mental hospital. Based on these investigations and on a century of clinical observations by many other students of this illness (Prichard, Henderson, Cleckley, Schneider, Maughs, Glueck and Glueck, and Gibbens et al.), the following clinical picture and natural history emerge. The outlines of this syndrome in terms of its clinical picture and natural history are now clear enough to characterize an illness or syndrome.

Clinical Description

Age of onset. The age of onset is before 15 years and probably, where an adequate history is obtained, before 12. The invariability of this early age of onset

is a diagnostic point of great importance and, in itself, excludes most of the other reasonably well defined psychiatric illnesses that sometimes begin that early in life but most often begin later, such as schizophrenia, manic-depressive reaction, anxiety reaction, and obsessive-compulsive reaction. It seems to the author of this section that the personality trait and personality pattern disturbances are so ill characterized that they cannot safely be said to exist in their described forms because of the absence of systematic detailed clinical and follow-up studies. Their ages of onset are, therefore, not relevant here.

Symptoms in childhood. The most frequent symptoms occurring in childhood—prior to ages 12 to 15—in persons who were later given the diagnosis of antisocial reaction include theft, incorrigibility (extreme disobedience, usually of parents), school truancy, running away from home overnight, having associates with bad reputations, staying out late, physical aggression, poor employment record in the somewhat older children, impulsiveness, reckless and irresponsible behavior with regard to time and place of its occurrence, slovenly appearance, nocturnal enuresis, lack of guilt, premarital sexual intercourse, pathological lying (lying that was not used to hide or minimize misbehavior), and homosexual activity (see Table I). In one study there was a median of seven such antisocial symptoms. A few childhood antisocial symptoms occurred either infrequently or did not reliably predict an adult antisocial reaction. These symptoms included, for example, vandalism, use of alcohol, and use of aliases. A median of four nonantisocial symptoms was reported in the same group. These symptoms included (besides enuresis, which should properly be classified as a nonantisocial symptom) sleep-walking, sleep-talking, irritability, nail-biting, poor eating, oversensitiveness, nervousness, being withdrawn and seclusive, odd ideas, unhappiness and depression, tics, and fears (see Table II). Each of these symptoms occurred in from 4 per cent to one third of the children who as adults were given diagnoses of antisocial reaction. The diagnosis of antisocial reaction for an adult was made without knowledge of the childhood symptoms. The symptoms differentially predictive of adult antisocial reaction are the antisocial symptoms listed in Table I, but proper emphasis should be placed on the finding that many of these same children had nonantisocial symptoms at the same time. *However, not a single child developed the antisocial reaction syndrome as an adult in the absence of antisocial symptoms in childhood.*

The number and variety of symptoms in childhood are as important in describing the natural history of antisocial reaction as are the specific individual symptoms themselves. If the number of childhood and juvenile antisocial symptoms was 10 or more, 43 per cent of these children developed the antisocial reaction syndrome as adults. But if the number of such symptoms was less than 3, only 4 per cent did (see

Table III). The significance of these findings cannot be fully appreciated from the numbers themselves. As the number of symptoms increased, the number of different areas of the patients' lives that were affected increased, so that, even in a child or juvenile, the antisocial disorder affects many areas of functioning. These patients exhibited disturbances in parental relationships, in relationships with their peers, in their sexual relationships, in their school behavior, in conforming to legal norms, in their sense of subjective discomfort (psychological and physical), in handling their aggressive impulses, in their general lack of responsibility, and even in the neatness of their appearance.

Even in the most antisocial group—10 or more antisocial behaviors and symptoms as a child—only about half the patients had developed the sociopathic personality syndrome as adults, as is shown in Table III. It should not be assumed that the remaining antisocial children who were not given the diagnosis of antisocial reaction were well as adults. Over 90 per cent of them were psychiatrically ill at follow-up. They showed a high prevalence of other adult psychiatric illnesses, especially alcohol addiction. Of those in whom 10 or more antisocial symptoms were present in childhood, only 5 per cent were clinically well as adults. In contrast, when there were fewer than 3 childhood antisocial symptoms, 34 per cent were clinically well as adults, even though they had attended a child guidance clinic when young. Thus, the occurrence of moderate to severe antisocial behavior in childhood is a serious prognostic sign with regard to adult psychiatric illness.

The factors that differentiate the children who will

TABLE III
Number of Antisocial Symptoms in Childhood and the
Diagnosis of Antisocial Reaction
as an Adult

The only significant correlations between number of childhood antisocial symptoms and adult diagnosis (other than antisocial reaction) were a direct one with alcohol addiction and an inverse one with anxiety neurosis. Of those children with six or more antisocial symptoms, 11 per cent were diagnosed as alcohol addicts as adults, and 8 per cent were diagnosed as having anxiety neurosis. Of those children with fewer than six childhood antisocial symptoms, only 4 per cent were diagnosed as having alcohol addiction, but 21 per cent were diagnosed as having anxiety neurosis. Other psychiatric illnesses, such as schizophrenia and hysteria, showed no significant relation between number of childhood antisocial symptoms and adult diagnosis. (Data from Robins, L. N. *Deviant Children Grown Up: A Sociological and Psychiatric Study of Sociopathic Personality*. Williams & Wilkins, Baltimore, 1966.)

10 or more	43	52	5

from those who will not develop the syndrome as adults are not understood or described satisfactorily. However, the families and environments from which the antisocial children have come will be described later in this section in an effort to ascertain differences between the children who do and the children who do not develop antisocial reactions as adults.

Symptoms in adulthood. The clinical picture of the patient diagnosed as a sociopathic antisocial reaction personality as an adult depends, in part, on the minimal criteria for making this diagnosis and on the criteria for excluding other psychiatric illnesses. In the studies of L. N. Robins and O'Neal (Robins, 1966) the diagnosis was based *only* on specified behavior and symptoms occurring after age 18—that is, excluding consideration of childhood and juvenile symptoms in making the adult diagnosis—and on the exclusion of patients whose antisocial symptoms occurred in the presence of any psychotic disorder or mental deficiency. Patients who were mentally deficient were arbitrarily excluded in order to obtain as homogeneous a group as possible.

The criteria for making the diagnosis of antisocial reaction required disturbances in a minimum of 5 of the possible 19 life areas described (see Table IV) and a clinical decision that the patient, regardless of the number of antisocial symptoms (as long as there were disturbances in at least five life areas), most

probably was suffering from an antisocial reaction and not from some other psychiatric disorder.

Somatic and behavioral but nonantisocial symptoms occurred with a significantly appreciable frequency in those diagnosed by Robins and O'Neal as antisocial personalities—31 per cent having more than 10 such symptoms or being disabled by them (Table IV). The specific symptoms noted in 5 per cent or more of these patients include anxiety symptoms (nervousness, anxiety attacks, dyspnea, palpitation), conversion symptoms (blindness, paralysis, trances, amnesias), depressive symptoms (suicide attempts, death wishes, chronic unhappiness), and many other somatic and psychological symptoms (see Table V).

In the Robins and O'Neal study, the vast majority of patients at follow-up were not seeking a physi-

TABLE IV

Adult Behavior and Symptoms of Patients given the Diagnosis of Antisocial Reaction

To be scored as positive, each of these disturbances had to be severe, as indicated, for example, by the criteria for marital history (two or more divorces, marriage to wife with severe behavior problems, repeated separations), arrests (three or more nontraffic arrests), sexual behavior (arrests on charges pertaining to sex, interview claims of extreme promiscuity—such as 50 different sexual partners—interview reports of homosexuality), impulsiveness (frequent moving from one city to another, more than one elopement, sudden Army enlistments, unprovoked desertion of home), financial dependency (totally or partially supported by relatives, friends, social agencies, or public institutions), and social isolation (does not participate in activities of any formal social group, sees friends less than once in 2 weeks, has no or only one close friend, sees less than 10 people socially). (Data from Robins, L. N. *Deviant Children Grown Up: A Sociological and Psychiatric Study of Sociopathic Personality*. Williams & Wilkins, Baltimore, 1966.)

cian's help at that time, and, as it turned out, only 12 per cent were in prison at the time of follow-up. Since most of the patients were not incarcerated at the time of follow-up, and since many other studies of persons with antisocial reactions have been on felons who were incarcerated, it seems important to include some aspects of the clinical picture seen in an incarcerated group, in one currently on parole, and in one on probation. The recent studies of Guze et al. present data on such groups. These prisoners (or parolees or probationers) showed early onset of antisocial behavior and of school difficulties. As adults, they exhibited, besides repetitive criminality, wanderlust or vagrancy, poor military records, poor job histories, poor marital

histories, belligerency and fighting, job difficulties, excessive alcohol intake, anxiety symptoms, conversion symptoms, drug addiction, suicide attempts, and sexual abnormalities. An investigation by Ehrlich and Keough of 50 patients diagnosed as having an antisocial reaction in a mental hospital showed that these patients had symptoms very similar to those in the studies of L. N. Robins and Guze.

Thus, whether studied when actively seeking medical help, when incarcerated, or when subjected to a follow-up study without the implications of current pressure for medical help or of current incarceration, there appear to be clear and striking similarities in the clinical picture of antisocial reaction in each of these ostensibly very different situations. Such a finding adds support to the concept of antisocial reaction as a specifically diagnosable illness with relatively well defined characteristics, even when these characteristics are elicited in different situations and presumably when the patients have differing motivations in imparting information.

Neurotic symptoms. Many investigators have commented on the presence of neurotic symptoms, especially conversion symptoms, in patients with antisocial reactions who came to them as patients. The observations of E. Robins et al. and others indicated that neurotic symptoms, including suicide attempts, occur in persons with antisocial reaction syndrome, whether or not they are actively seeking medical assistance at the time observed, and that these symptoms form part of the clinical picture of antisocial reaction. Jenkins, in an analysis of the personality disorder cases in the Brill and Beebe study, also emphasized the high prevalence of neurotic symptoms in patients given the diagnosis of antisocial reaction.

In those patients who later improved (see under "Prognosis"), there was no increase in neurotic symptoms following improvement. Giving up adult antisocial behavior is, therefore, *not* associated with an increase in numbers and kinds of neurotic symptoms. This finding indicates that acting out—that is, antisocial behavior—is not a substitute for neurosis. When those patients who had more than nine somatic or psychologically uncomfortable symptoms or who were disabled by somatic symptoms (31 per cent in Table IV) are compared with the patients who had nine or fewer such symptoms and who were not disabled by them (69 per cent), it is evident that the greater the number and variety of antisocial symptoms, the greater the number of or disability from neurotic symptoms. Of those patients with nine or more antisocial symptoms, 40 per cent had a large number of disabling neurotic symptoms; of those patients with eight or fewer antisocial symptoms, only 25 per cent had a large number of disabling neurotic symptoms. It appears, therefore, that a person with antisocial symptoms will have more neurotic symptoms the more antisocial symptoms he has, and he will

have fewer neurotic symptoms the fewer antisocial symptoms he has.

Psychological attributes. The conceptions of antisocial reaction that emphasize primarily such qualities as inability to learn from experience or punishment, callousness, lack of responsibility, poor conscience, egocentricity, lack of guilt, self-hatred, extreme narcissism, pregenital fixation, absence of generous emotions, absence of psychological conflict, lack of judgment, ability to rationalize one's behavior, incapacity for loyalty, and warped capacity for love are not presently useful either clinically or in research on this syndrome. Each of the above qualities is difficult to define and can be ascertained only from statements made by the patient about himself or by a relative about the patient or by inferences from his behavior. Since patients and relatives rarely make such observations, these psychological attributes can ordinarily be inferred only from the patient's behavior. These inferences are probably correct in many instances, but, being only inferences, they are subject to much more serious error than is the direct reporting of symptoms and behavior. Because of the errors of reliability and validity to which these psychological attributes are subject, they form a poor structure on which to base a definition of antisocial reaction. These inferred attributes are merely convenient summaries and are not a more profound analysis of antisocial reaction than is directly observable behavior. Indeed, these attributes are probably less profound because some are demonstrably incorrect, such as absence of psychological conflict if this implies absence of neurotic symptoms, and others have no demonstrated evidential basis. A more profound analysis is made possible by defining the syndrome in terms of reliably identifiable symptoms and behavior that permit clinicians and research workers to select homogeneous groups of patients to study.

Sex Incidence

The sex incidence of antisocial reaction is preponderantly male, whether observed as children or adults, in prison or out of prison, in a medical setting or not. The degree of preponderance in males has not been quantitatively established but may approximate 5 or 10 males to 1 female.

Etiology

The etiology of antisocial reaction is not known at present. Part of the reason that the etiology is not known may be that our techniques for studying causes are primitive. Another part of the reason may be that the syndrome has only recently been precisely enough defined to permit the study of a homogeneous group.

Physical factors. Despite numerous electroencephalographic (EEG) studies indicating varying but high rates of abnormality in adult criminals, there is no proof that brain damage or abnormality as reflected

in the EEG is a necessary precondition for the development of antisocial reaction. Genetic studies by the twin method or the contingency method are lacking. Although there have been a few studies of the genetics of criminality, these have not decisively settled the nature-nurture controversy.

Environmental factors. Almost all investigators, whether interested primarily in the environment, intrapsychic dynamics, or the gene, agree that there is a high family prevalence of antisocial reaction or alcoholism. Whether this familial loading is primarily genetic or environmental is still unsettled. It may be an almost equal interactive effect of nature and nurture.

The families and environments from which patients with antisocial reaction syndrome come have been noted by many students of the disease to show a high rate of antisocial behavior, broken homes, alcoholism, and low socioeconomic status. Most of these observations have been retrospective, but the general agreement strongly suggests the validity of these findings. L. N. Robins and O'Neal obtained data concerning the families of patients destined to develop the syndrome of antisocial reaction as adults while these patients were still children, thereby avoiding any retrospective bias.

Although the best predictors of the development of antisocial reaction syndrome as adults are the frequency, severity, and variety of antisocial symptoms of the patients as children, these are by no means perfect predictors, as shown in Table III. Do other identifiable childhood factors give additional aid in predicting which children will go on to develop an antisocial reaction as adults and which ones will not? Are such childhood conditions as broken homes, quality of parental discipline, parental antisocial behavior, low socioeconomic status, and quality of neighborhood related to the causes of antisocial reaction, or are they merely associated phenomena with minimal or no causal impact? (Causal in this context means a necessary precondition, whether or not it is sufficient.)

The answer to the first question is that, in the more severely antisocial children (those with six or more such symptoms), only two nonantisocial factors—being male and having no parental discipline or parental discipline that was inconsistent or excessively lenient—were related to the development of an antisocial reaction syndrome as an adult. Each of these two factors tended to increase slightly but significantly the proportion of severely antisocial children who developed antisocial reactions as adults. In the milder antisocial children (those with fewer than six antisocial symptoms), the only family and environmental variable that led to increased proportion of patients diagnosed as antisocial as adults was having an antisocial or alcoholic father.

The answer to the second question is that the association of antisocial reaction and each of the factors ordinarily thought of as associated with the syn-

drome (broken home, antisocial or alcoholic parent, etc.) was once again confirmed in the study of Robins and O'Neal, in which the children were studied and the factors assessed prior to the knowledge of whether or not the patient had developed antisocial reaction syndrome as an adult. Whether these same factors are causal cannot be ascertained because they are not independent of antisocial behavior in the child. If some of these factors are causal, they must be mediated through the occurrence of antisocial symptoms as a child. In the absence of childhood antisocial symptoms, broken homes, sociopathic or alcoholic parents, poverty-stricken neighborhoods, living in slum areas, etc., do not lead to adult antisocial reaction syndrome. In addition, it was found that middle and lower class antisocial children did not differ from each other in the proportion developing antisocial reaction syndrome as adults if they had similar frequency and severity of antisocial behavior as children, even though in the middle class children most of the negative environmental factors were absent. These findings suggest that many or most of these associated factors are not necessary causes. There is no proof, one way or the other, at present.

Differential Diagnosis

The differential diagnosis of antisocial reaction from other psychiatric illnesses is based on manifestations of antisocial behavior. In illnesses where antisocial behavior is rarely or never a manifestation, as in anxiety neurosis, the question of differential diagnosis seldom arises. In contrast, where antisocial behavior is a common or major manifestation of a syndrome, as in alcoholism, the question of differential diagnosis arises frequently. This discussion of differential diagnosis is predicated on the assumption that complete information is generally available for each patient. Since this is often not the case, the differential diagnosis becomes more difficult. It is especially necessary, therefore, to obtain outside information from relatives and from records to diagnose the antisocial reaction properly.

The characteristics of antisocial behavior and related manifestations in antisocial reaction that most help to make a positive diagnosis of the syndrome include: (1) the invariability of the early age of onset, always before age 15 and probably before age 12; (2) the frequency, variety, and severity of the antisocial behaviors manifested; (3) the large number of life areas involved by the symptoms, such as troubles with peers, legal difficulties, marital difficulties, sexual abnormalities, impulsiveness, irresponsibility, poor military record, poor employment record, and financial dependency; (4) the repetitiveness and chronicity of the antisocial acts, which make it difficult to find periods of temporary remission of antisocial activity enduring even a few months; (5) the inferred psychological attributes underlying these behaviors, such as callousness, egocentricity, lack of

deep attachments, and lack of loyalty; and (6) the absence of another psychiatric illness that could explain these diagnostic attributes.

Alcoholism. The most difficult syndrome to differentiate from antisocial reaction is alcohol addiction (chronic alcoholism). There are three chief reasons for this difficulty. First, the behavior of alcohol addicts with regard to arrests, imprisonment, marital difficulties, sexual difficulties, fighting, irresponsible and undependable behavior, lying, rationalization, and neurotic symptoms is similar to these behaviors and symptoms in adults given the diagnosis of antisocial reaction. Second, approximately three quarters of patients given the diagnosis of antisocial reaction as adults are alcohol addicts or at least excessive drinkers. Third, in adults it is frequently difficult to obtain a childhood history that unequivocally demonstrates the onset of antisocial behavior prior to the onset of drinking. Without this information, with the knowledge that adult patients with alcohol addiction behave in a fashion similar to those with antisocial reaction syndrome and with the knowledge that the majority of adult patients who are antisocial drink to excess, it is very difficult and frequently impossible to determine which disorder appeared first. Only in the minority of patients given the diagnosis of antisocial reaction who do not drink alcohol to excess and in the minority of alcohol addicts who manifest little or no antisocial behavior is it possible to differentiate the two syndromes easily.

Manic-depressive reaction. The differentiation of antisocial reaction from the manic phase of manic-depressive reaction rarely presents a difficult problem, even though a patient with mania may manifest many antisocial symptoms during a manic episode. The relative ease of differentiation depends primarily on two factors: (1) The natural histories of the syndromes are vastly different. Mania is episodic and rare in childhood, and between episodes a patient with mania is not antisocial. (2) The mental status in mania—euphoria, clang associations, flight of ideas, etc.—is very different from that in antisocial reaction. The only possibility of confusion between the two syndromes would be if there is a chronic hypomania that manifests itself as antisocial reaction. The occurrence of this situation could only be decided by long term follow-up and family studies. A large number of Prichard's original cases of moral insanity were instances of what today would be diagnosed as manic-depressive reaction.

Schizophrenia. The differentiation from schizophrenia presents a problem because some patients with schizophrenia present antisocial behavior as part of their disease. The problem in differentiation is generally resolved easily by taking into account the natural history of each illness and the positive manifestations of schizophrenia—delusions, hallucinations, affective blunting, formal thought disorder, etc. In the author's view, antisocial reaction with psychosis is

usually Ganser's syndrome or, in very rare instances, a coincidental occurrence of two separate illnesses in the same patient.

Chronic brain syndrome. The necessity for differentiating antisocial reaction from chronic brain syndrome is based on the finding that a few cases of chronic brain syndrome manifest antisocial behavior. Once again, the natural history of each syndrome; the presence of disorientation, confusion, memory loss, and intellectual deterioration in those with chronic brain syndrome; and the age of onset make the differentiation of the two syndromes rather easy.

Neurosis. The occurrence of neurotic symptoms in antisocial individuals sometimes raises the question of whether the patient suffers from a neurosis or antisocial reaction. The primary point of differentiation is the total or virtual absence of antisocial symptoms in the anxiety reaction, obsessive-compulsive neurosis, and hysteria. The only exception is that some women with hysteria show antisocial symptoms early (ages 12 to 16) in the course of their illness. But, as adults, even these women show little or no antisocial behavior. As long as one avoids unnecessary arguments with regard to the etiology of antisocial reaction, there is little problem in clinical differentiation of antisocial reaction and neurosis.

Personality trait and personality pattern disturbances. The attempt to differentiate antisocial reaction from personality trait and personality pattern disturbances is, in the author's estimation, a futile exercise at present because there are no detailed and systematic studies of the latter syndromes. Generally, the essential point is alleged to be that antisocial behavior is not a chief manifestation of the personality pattern and personality trait disturbances.

Dyssocial reaction. The differentiation of antisocial reaction from dyssocial reaction, as presumably seen in the professional criminal, is ambiguous because the use of the term "dyssocial reaction" implies an etiological diagnosis. Since the etiology of dyssocial reaction has not been demonstrated and since, even if it exists, it may not be a psychiatric illness but only a condition of life, the discussion of a clinical differentiation seems at best unwieldy and at worst misleading.

Malingering. A discussion of the differential diagnosis of antisocial reaction would be incomplete without a discussion of the vexing question of malingering. The presence of malingering is difficult to demonstrate. An allegation or suspicion of malingering also implies, perhaps not necessarily but at least psychologically, an unprofessional attitude for a physician to take towards a patient. Despite these serious reservations, it is the author's impression that malingering is more common in antisocial individuals than in any other definable psychiatric syndrome. Malingering probably occurs most often when the patient has a direct gain in the offing, e.g., avoidance of arrest or prosecution, obtaining money, or avoiding military service. Ma-

lingering, however, is probably not limited to patients with antisocial reaction and almost certainly does not occur in each antisocial patient in each situation noted above. Malingering is a complex phenomenon that has yet to be properly studied. Nevertheless, in antisocial patients, malingering does occur and, when it does, may take the form of a psychiatric, medical, or surgical disease.

Treatment

The optimal treatment for antisocial reaction is unknown. So far as the author is aware, there are no controlled, documented studies to indicate the superiority of any form of treatment—whether psychotherapy, behavior therapy, psychoanalysis, drug therapy, electroconvulsive therapy, or frontal lobotomy—over any other. The absence of the proof of efficacy of a given specific treatment does not necessarily imply that a psychiatrist may not help the patient and his family in decisions concerning management. On the other hand, even this more limited goal has not been clearly shown to be facilitated by psychiatric care.

Prognosis

Remission and improvement apparently do occur in patients who suffer from antisocial reaction. The Gluecks showed some time ago that the extent of repetitive criminality diminishes with age.

In their studies at that time it was not clear that they were dealing with the antisocial reaction syndrome; it was only clear that they were dealing with criminality. The more recent studies of L. N. Robins and O'Neal dealt with persons given a diagnosis of antisocial reaction. The median age at which significant improvement occurred in their antisocial behavior was 35 years. A total of 39 per cent had shown improvement. Of those who had improved, one fifth did so before age 30, three fifths between ages 30 and 45, and one fifth after age 45. The decade of greatest improvement, which included half of all those who improved, was from ages 30 to 40. The improvement in gross antisocial behavior was not necessarily associated with having become particularly well adjusted. Many still reported interpersonal difficulties; irritability; and hostility toward spouse, neighbors, and organized religion.

The relation of life events to improvement is unclear. The most common reasons offered by the patients for their improvements were maturity, marriage, fear of imprisonment, and increased responsibilities. Only about one fifth named an individual as influential in their improvement, and in almost all these instances a spouse was named. No person named a psychiatrist, minister, social worker, parole officer, or other professional person.

The finding of remission or improvement in about one third of these patients indicates that even established adult antisocial reaction can improve. This tends to make uncertain the meaning of statements

concerning antisocial patients, such as that these persons "profit neither from experience nor punishment, and maintain no real loyalties to any person, group or code" (from the *Diagnostic and Statistical Manual*).

Suggested Cross References

For information regarding fundamental concepts of sociocultural and family determinants of behavior and personality see Fleck's section on the family (Section 4.3), Silverman's section on sociology (Section 4.2), and Wallace's section on anthropology (Section 4.1), all in Area B, on the basic behavioral sciences. It should be noted that in this section evidence was adduced to indicate that there is no documented evidence that sociological factors play a causal rather than a secondary role in the genesis of antisocial reaction. Alcoholism is discussed more fully by Chafetz in Section 27.3. Sociopathic behavior in children is covered by Stubblefield in Section 41.4, and Freedman covers the sociological determinants in juvenile delinquency in Section 41.5.

Sexual Deviations

26.2 SEXUAL DEVIATIONS. I: INTRODUCTION

IRVING BIEBER, M.D.

Terminology

The sections that follow would have been entitled "Sexual Perversions" 25 years ago. With the development of greater methodological and conceptual sophistication, it is now recognized that the term carries with it a moralistic connotation that is entirely inappropriate for scientific description and categorizing. And since there is no consensus among biological and behavioral scientists that certain types of sexual behaviors are pathological, the more general term, deviance, has come into usage. Nevertheless, as applied to psychiatric syndromes, *deviation* has, for the most part, become synonymous with pathology. The following sections deal with behaviors that are both pathological and deviant.

Whenever the term deviation is used descriptively or diagnostically in this section, a statistical connotation is implicit. In this sense, deviation is a statistical function involving movement away from the median or statistical norm; it does not imply pathology. Statistically, genius is as deviant as mental deficiency; sterility in a woman is as deviant as the bearing of 15 children. Sexual behavior may be pathological and not deviant or deviant but not pathological. Exclusively monogamous love relationships in marriage may be statistically deviant in our society, yet they are hardly pathological. During the Victorian era and well into recent times, sexual frigidity seemed to be the statistical norm, though frigidity is clearly pathological, as has been substantiated by the recent work of Masters and Johnson, who demonstrated the high orgasmic potential of women. The statistical norm cannot by itself be taken as a criterion of the presence or absence of pathology.

The concept of cultural norm, a variant of the mathematical norm, does not bring us any closer to a solution. According to the cultural concept, the standard of what constitutes psychopathology is a relative, not an absolute, one. Each society determines what behavior shall be deemed normal and what abnormal, based on how it fits into the social context. Hence, it is argued that homosexuality is considered abnormal in Western society only because the cultural ethic designates it as such. The cultural relativists reason that, if

societal attitudes toward homosexuality were as accepting as toward heterosexuality, inversion would not be pathological. This point of view contrasts sharply with the argument advanced here—that the health or pathology of behavior must ultimately be assessed in relation to optimal individual and group development and continuity, not on the basis of conformity to a cultural norm, though as the sciences move forward, concepts of optimal individual and group development change. In certain primitive societies infanticide was an accepted practice, but no serious scientist would defend its normative function, even for purposes of population control. Normative practices among primitive peoples also include ritual killing, cannibalism, bizarre sexual rites, and so forth. But such practices are based on irrational, magical beliefs that do not further health and development. Investigators of human behavior continually seek for data among groups and societies that may reveal prevailing attitudes and behavior; however, the modal types that establish statistical norms are not necessarily indicators of an absence of pathology.

The Role of Fear

Psychoanalysis offers a methodology and criteria for assessing sexual psychopathology. A basic assumption is that dysfunction in heterosexual intercourse and orgasm indicates a neurotic disorder. Where fear of heterosexual gratification plays a significant role, the emergent sexual behavior is pathological. Fears of one sort or another determine varying degrees of frigidity in women or potency difficulties in men. Fears may determine dramatic behavioral inventions, circumventions, and shifts in sexual patterns, as may be noted in homosexuality, where sexual gratification is preserved but fear is avoided by a renunciation of heterosexuality. The sexual masochist insures gratification by incorporating into the sexual act the pain that is symbolic of the punishment and injury anticipated as reprisal for his having engaged in sexual activity and erotic pleasure. The hope of finding stimuli intense enough to break through sexual inhibitions leads some individuals to seek out various esoteric sexual practices. The many varieties of psychopathological sexual behavior attest to the imagination and adaptability of man, but these forms rotate around the axis of fear.

In *Three Essays Toward a Theory of Sexuality*, Freud implied that heterosexual behavior terminating in sexual intercourse and orgasm was normal. Sexual behavior terminating in orgasm in situations

other than heterosexual intercourse was designated as a deviation, aberration, or perversion. If, for example, orgasm were to follow masturbation or heterosexual oral practices, Freud would have considered it to be perverse, though not necessarily pathological. He viewed behavior as pathological only if it was part of a habitual pattern: "If a perversion instead of appearing merely *alongside* the normal sexual act and object, and only when circumstances are unfavorable to *them* and favorable to *it*—if, instead of this, it ousts them completely and takes their place in *all* circumstances—if, in short, a perversion has the characteristic of exclusiveness and fixation—then we shall usually be justified in regarding it as a pathological symptom."

Most psychiatrists agree with Freud that where orgasm is habitually achieved without heterosexual intercourse, a pathological condition exists. A wealth of clinical data from psychoanalysis demonstrates that in those instances where sexual behavior does not include heterosexual intercourse, fear and inhibition have determined the exclusion. However, the activities that have led to orgasm may or may not be pathological. Masturbation, for example, can be one normal mode of sexual expression for both sexes throughout life. The same holds for fellatio and cunnilingus, which may make up part of the normal sexual repertoire. Many individuals who participate in such practices suffer shame and guilt because they have been taught that the practices are wrong, sinful, dirty, and so forth. If a physician is consulted, he must correct any such erroneous ideas, thus freeing the patient from unnecessary guilt feelings. When masturbation and oral practices constitute the major if not the sole activities of sexual life, it is not the activities as such that are pathological but rather the existing fears which exclude the capability for heterosexual intercourse.

The central role of fear in the pathological scheme of things requires diligent attention in the treatment of sexual disorders. Underlying unrealistic beliefs must be delineated to resolve the fears rather than to terminate the activities. The latter approach is based on the spurious notion that sexual energies that should be available for intercourse are misdirected and wasted in the perversions. Attempts to interdict homosexuality or any other sexual act deemed to be pathological do not facilitate the restitution of heterosexual intercourse; only the resolution of fear accomplishes this.

Certain sexual activities are, however, always to be considered as pathological—such as sadistic sexual behavior, where the infliction of physical or psychic pain is a necessary component, and its counterpart, sexual masochism, where the experience of pain is a necessary element. Other bizarre activities, such as bestiality and necrophilia, are obviously abnormal.

Freud classified sexual aberrations as (1) deviations linked to the sexual object and (2) deviations linked to the sexual aim. He defined sexual object as the person toward whom one is sexually attracted, and

sexual aim as the act through which the instincts tend to find expression. Under the category of deviation in respect to the sexual object, Freud included homosexuality, the choice of sexually immature persons, and the choice of animals. Under deviations in respect to the sexual aim he constructed two subcategories: anatomical extensions and fixations of preliminary sexual aims. Subsumed under anatomical sexual extensions were the behaviors that include the use of nongenital organs as genitals, such as the mouth and the anus, and personal possessions and parts of the sexual object, such as articles of clothing, or a foot, or perhaps an ear, as stimuli for sexual excitation. Preliminary sexual aims refer to the various aspects of sexual foreplay preceding intercourse. Freud posited that any interference with or fear of participating in sexual intercourse could determine a fixation on some aspect of the foreplay, thus converting the foreplay itself into a substitutive sexual aim. He emphasized touching, looking (scopophilia), sadism, and masochism.

Freud's Explanatory Theories

Freud developed a complex metapsychological theory to explain sexual perversions. Two major components of the theory were found by him to be particularly applicable—the bisexual and the libido theory.

Bisexual theory. Freud did not evolve the bisexual theory; it was current in the psychiatric circles of his time. It held that each individual was part man and part woman. But Freud added his original stamp to the theory by identifying masculinity with activity and femininity with passivity. Experiential as well as constitutional factors were assumed to determine how much of each component would exist in the mature adult. In the normal male, the major part would be masculine and active; in the normal female, the major part would be feminine and passive. The part opposite to the biological sex assignment was thought to constitute the source of perversions. Thus, it would be perverse for a male to harbor any significant quantity of passive strivings and for a female to have a preponderance of active strivings.

Libido theory. Freud originated the libido theory to explain sexual development, sexual process, and sexual psychopathology. According to this theory, the sexual instinct in its development from infancy through adult life goes through several phases of maturation. Each phase is dominated by a somatic organ; each of the oral, anal, phallic, and genital phases unfolds under the aegis of its organ counterpart. Freud postulated that there were erotogenic organs which were linked to various developmental stages and that these organs were the somatic loci for operant processes of the sexual instinct. During the earliest stage, the mouth was identified as the locus of the sexual instinct. Supposedly, a continuous endosomatic stimulation emanates from the mouth, creating a demand on the psychic life of the infant. In this oral phase, the

demand motivates that behavior which brings to the mouth appropriate, gratifying stimuli, such as the mother's breast and food.

Each stage and its organ representative supposedly have specific and particular demands. If, as development proceeds, the demands falling to any particular stage are inappropriately met—that is, insufficiently or excessively met—fixations at that stage then occur. The psychic demands issuing from the infantile erotogenic organs continue on into adult life. In normal sexual development, according to Freud, the infantile libidinal organs and phases do not become fixated at early levels but during the final genital phase become organized under the dominance of the genital organs, the appropriate locus of the sexual instincts from puberty on. Thus, fixation at an earlier level, say the oral level, means that there has been a continuity into adult life of anachronistic demands for oral gratification. Such demands provide the motivating force and psychic energy for perverse impulses and behavior. Oral sexual practices, both heterosexual and homosexual, are explained by this theoretical construct.

Freud connected all adult perversions with anachronistic infantile impulses; he then drew two additional corollaries. (1) Neurotic symptoms are rooted in perverse impulses. Such symptoms are the negative or counterpart of the perversion. Some individuals express perverse impulses in action, others in neurotic symptomatology. The tendency to *act out* the perverse impulse is characteristic of the psychopath while the tendency to translate the impulse into *neurotic symptoms* is characteristic of the neurotic. (2) The tendency to harbor perverse impulses is universal, since each individual is bisexual. Freud thought that it was unlikely that the development of the sexual instinct proceeded without vicissitudes. In the normal person perverse impulses are mediated by means of repression and sublimation, so that acting out does not occur and the perverse impulses are not translated into neurotic symptoms.

Other Explanatory Theories

Freud's libido theory continues to be accepted as a workable conceptual framework in classical psychoanalytic theory, though in the past 25 years it has met with considerable criticism. Many psychiatrists and psychoanalysts no longer accept the libido theory as explanatory either of sexual or of general psychopathology. Among the alternative theoretical systems to evolve over the years, three have gained prominence in American psychiatry: the cultural theory, its major exponent being Karen Horney; the adaptational theory emphasized by Sandoz Rado; and the interpersonal theory promulgated by Harry Stack Sullivan. Each of these theorists has attempted to explain sexual psychopathology in adaptational terms; their views differ essentially as regards a conception of *what the individual is adapting to*.

Interpersonal theory. In this theory, sexual psychopathology is conceived of as both a manifestation of a pervasive derangement in interpersonal relationships expressed in the sexual sphere and as an adaptive way of selecting a type of sexual organization commensurate with optimal interpersonal expressiveness.

Cultural theory. The culturalists assume that beliefs, mores, and values characteristic of the society in which one is reared are reflected in individual psychology and psychopathology. Three such ongoing cultural characteristics are exploitiveness, competition, and authoritarianism, which may find expression in pathological sexuality and other aspects of behavior. The culturalist hypothesizes that sexual psychopathology is a manifestation and an expression of the cultural trends inimical to optimal human relatedness. Through the sexual process an adaptation is made to express or defend oneself against exploitiveness, competition, authoritarianism, and other antisocial trends.

Adaptational theory. As it relates to sexual psychopathology, this theory is predicated on the assumptions that abnormal sexual behavior is a consequence of fear of heterosexual intercourse and heterosexual relatedness, particularly with a loved and valued object; that the determinants of fear emerge from deleterious life experience, from which derive faulty beliefs and belief systems supporting erroneously based fears; and that the variegated pathological sexual behaviors are an adaptation to fear. Pathological sexual behavior is directed toward preserving sexual gratification while attempting to cope with the threat of anticipated injury by engaging in a series of adaptive maneuvers usually referred to as defenses.

The defenses may circumvent the threat or combine the threat with a defense and include both in the sexual act itself, or they may deal with the threat in a variety of other ways. In homosexuality, threat is avoided by substituting a homosexual object for a heterosexual object, which is perceived as threatening. In masochism, the threat of punishment for heterosexuality and the concretized punishment—that is, the painful component of the masochistic act—are made part of the sexual behavioral sequence so that orgasm is not inhibited by fear. Rado refers to such a pattern as pain-dependent behavior.

In sum, psychopathological sexual behavior is organically goal-oriented and is integrated with a variety of defensive and reparative maneuvers as a way of adapting to an expectation of attack for engaging in heterosexual activity, particularly with a loved object. The determinants of the fear, the beliefs underlying the expectation of punishment and damage to self, and the nature of the anticipated attack develop during childhood and adolescence. This neurotic fear derives from three major sources: (1) inappropriate, prohibitive attitudes and behavior by parents and other authority figures toward the child's expanding sexuality; (2) maladaptive parental atti-

tudes and behavior toward a child's oedipal manifestations; and (3) parental interference with normal sexual identification and failure to reinforce gender identity. The anticipated attack may include physical injury—such as castration, bodily assault, even murder—and social injury—such as rejection, humiliation, and degradation—in short, any set of circumstances or acts deemed to be antithetical to the best interests of the self.

Another category which may be considered pathological concerns sexual behavior oriented to nonsexual goals. An analogy to eating is relevant. Normally, eating satisfies the feelings of hunger that arise from metabolic processes. But if an individual eats as a way of relieving tension or boredom, such eating is compulsive and neurotic. If sexuality becomes a way primarily of relieving anxiety and tension or as escape phenomena either from work or other anxiety-laden situations, or where sex becomes an opportunistic maneuver to gain affection or approval, or where sex becomes a way of dominating one's partner, such behaviors must be construed as neurotically inspired. Prostitution is a prime example of the use of sexuality for gains other than sexual gratification. The prostitute also suffers from sexual inhibitions and fears which preclude stable heterosexual love relations with appropriate love objects. Where sexuality is used for purposes other than erotic gratification, one can usually delineate anxiety and inhibition surrounding the attainment of a meaningful love relationship.

Normal Sexuality

If the criteria for diagnosing pathological sexual behavior are basically those of determining the areas of irrational, inhibiting fears, what are the criteria of normal sexuality? Are they simply the absence of pathology and the absence of fear? Or is normal sexuality something that can be described as a viable process? Optimal sexual functioning excludes, of course, irrationally based fear and inhibitions. But since man is a biosocial organism, the nature of his relatedness to a love object is central in determining the criteria. In this writer's view, a healthy sexual adaptation includes the capacity to engage in sexual experiences without fear or guilt and at an appropriate time to fall in love and marry one's chosen partner and to sustain one's feelings of love and sexual attraction to the spouse. The mate will have no preexisting or predictable disorder of a serious kind and no known difficulties that would disrupt, distort, or negate a happy relationship. It is not implied that a couple must maintain a state of constant euphoria and ecstasy but rather that there be the capability of remaining in good emotional contact with each other; of having mutual respect, mutual pride, a sense of identity of interests, and respect for each other's integrity, individuality, and privacy; and of having expectations of

each other which are realistic and free of opportunistic strivings.

Sexually, the male is expected to be potent and orgasmic, with frequency of intercourse determined by mood, mutual agreement, circumstances, and needs. The female is expected to be responsive and orgasmic and to feel as free to initiate sexual activity as does the male. Sexuality should be enthusiastically enjoyed, and each should be capable of having frank discussions about sexual matters. Both partners should have a wish for children and the psychological ability to implement such wishes. When children become members of a family group, husband and wife should be able to relate lovingly, understandingly, and impartially to offspring of either sex, yet parents should be able to respond to the individual differences and requirements of each child.

Problems relating to falling in love, sustaining a love relationship in or out of marriage, resistance to marriage, and psychological sterility are generally not regarded as sexual deviations. Yet such problems are the most common manifestations of sexual fears. The bizarre and esoteric deviation stands out, is more visible, and commands one's attention and curiosity more insistently than the more chronic, persistent, widespread disorder, which tends to lose itself within the culture.

Suggested Cross References

For further information regarding normal sexuality see Section 5.7 in Area B, on the basic behavioral sciences. In Area C, Mack and Semrad's chapter on classical psychoanalysis (Chapter 6) contains a more detailed discussion of analytic concepts mentioned in this section, such as libido, psychosexual stages of development and the theory of bisexuality. In that same area also see the sections on Horney, Sullivan, and Rado (Sections 7.2, 7.3, and 7.5, respectively) for more detailed discussions of their theoretical positions and their alternate viewpoints on sexuality.

26.3 SEXUAL DEVIATIONS. II: HOMOSEXUALITY

IRVING BIEBER, M.D.

Definition

Definitions in psychiatry, as in science generally, tend to reflect one's conceptualizations about his subject. Homosexuality is defined here as an adaptation characterized by sexual behavior between members of the same sex.

This seems straightforward enough, but one may ask, "What does sexual behavior include?" If one man puts his arm around another as an expression of warmth and affection, if two women greet each other by kissing, are these gestures expressions of sexuality? Most psychiatrists would not designate such behavior as sexual unless erotic interest and excitement could be demonstrated as motivational elements. Yet it is often difficult to establish motivation, particularly when the participants lack conscious awareness of erotic feelings. Would one classify as homosexual the masturbation of preadolescent and adolescent boys in a group? Certainly the activity in this instance is overtly sexual, and only males are involved, but this experience is onanistic: it is transpiring *among* males, not between any two. It is of clinical interest that habitual homosexuals rarely have a history of having participated in group masturbation. In the view of this writer, early masturbation in groups is not homosexual, though this opinion is not unanimously shared. However, despite differences about acceptable diagnostic criteria, there is consensus that those who exclusively and preferentially engage in same sex erotic activity are homosexuals.

What about married men who involve themselves in homosexual behavior from time to time? Or those who engage in it when separated from the opposite sex, as occurs in prisons? Or the homosexual prostitute, whose sole aim presumably is monetary gain? Are these men true homosexuals? If not, what are they?

Kinsey et al. attempted to solve this theoretical and methodological problem by rating the extent of homosexual activity rather than by designating the respondent as a homosexual or a heterosexual. A seven-point scale was constructed to determine a heterosexual-homosexual balance. Respondents who scored zero had had neither homosexual responses nor experience; those who scored three were about equally heterosexual and homosexual; six was scored by exclusive homosexuals.

Another attempt to establish a valid guidepost for diagnosis was offered by Marmor, who has stated:

The clinical homosexual [is] one who is motivated in adult life by a definite preferential erotic attraction to members of

the same sex and who usually (but not necessarily) engages in overt sexual relations with them....The definition does, however, exclude patterns of homosexual behavior that are not motivated by specific preferential desire—the incidental homosexuality of adolescents or the situational homosexuality of prisoners and sailors....Most members of such groups... who turn, or return, to exclusive heterosexuality as soon as the opportunity arises, are not homosexuals psychodynamically....

According to this construct, consciousness of preferential homosexual desire is required for the classification, but it does not take into account one decisive point: An adult who repetitively engages in homosexual activity may be erotically responsive though awareness of it is repressed. Repetitive experiences establish the existence of a homosexual pattern, whether or not it is perceived as preferential. An adult who repetitively engages in homosexual behavior must, therefore, be designated as homosexual. Those who also engage in heterosexual activity are termed bisexual. They may be predominantly homosexual or predominantly heterosexual. The latter, nevertheless, have the tendency under certain conditions to shift into a homosexual gear; that is, they have the capability for homosexual arousal and behavior. This readiness for inversion differentiates men who engage in sporadic, infrequent, or even rare homosexual encounters from exclusive heterosexuals.

Male Homosexuality

Although homosexuality occurs in both sexes, male homosexuality has been accorded the major attention by theologians, jurists, historians, and other behavioral and social scientists.

Prevalence. Although it existed in ancient civilizations and is widespread in modern society, homosexuality seems to have been absent or rare in some cultures in the past, and there is little or no evidence of it in certain present day societies. The incidence and prevalence of homosexuality in the United States is unknown. Because of the opprobrium associated with inversion, accurate statistics are difficult, if not impossible, to obtain. Kinsey et al. contributed the only systematic statistical studies in this country. According to their findings, about 4 per cent of white adult males remain exclusively homosexual after adolescence, and about 10 per cent are "more or less exclusively homosexual for at least three years between the ages of 16 and 65." At least 37 per cent of the total male population was reported to have had overt homosexual experiences with or without orgasmic culmination at some time between puberty and old age. In preadolescence the incidence of homosexual genital play was reported as 48 per cent, and this percentage increased if nongenital activity was included. Kinsey's definition of homosexuality is very broad. Behavior such as group sexual experimentation is not necessarily homosexual; therefore, if homosexuality is loosely defined, the exceedingly high incidence of behavior reported as homosexual may be inflated.

The psychiatric examination of large numbers of patient and nonpatient populations screened for military service reveals far lower estimates, varying from 1 per cent to 5 per cent. In World War II, 10 million men were involved; they ranged in age from 18 to 45 and over. The overall figures show that about one tenth of 1 per cent were rejected by draft boards for homosexuality. About 0.4 per cent were turned down at induction centers, and about as many more were subsequently discharged for homosexual activity while in active service. In total, about 1 per cent of the Armed Forces were officially identified as homosexual. A proportion of homosexuals likely escaped these surveys; still, an extravagant estimate of those who were missed would be, say, another 1 per cent, bringing the total to 2 per cent. The estimate that 1 to 2 per cent of male adults are exclusively or predominantly homosexual accords with this writer's experience as a psychiatrist in civilian practice and in the Army. In a study of thousands of German males, a research work that endured over the first 2 decades of this century, Hershfield estimated that 2.3 per cent were exclusively homosexual and 3.4 per cent were bisexual. Clearly, homosexuality is relatively uncommon, but since the behavior of overt homosexuals is highly stylized and frequently exhibitionistic, there is often an overestimation of its prevalence.

Inversion is widely distributed and cuts across caste and class lines. There seems to be some underrepresentation among Jews, but whether second generation and third generation Jewish-Americans are less affected than the general population remains to be determined. Homosexuality appears to be overrepresented in occupations such as acting, dancing, and hairdressing, but in general it is not restricted to any occupation or stratum.

Characteristics. Male homosexuals differ from each other as do heterosexuals, but they have in common the homosexual proclivity and an inability to form or sustain an orgasmically effective, romantic heterosexual relationship. However, two major groupings of homosexuals may be noted: one consists of men who are exclusively and predominantly homosexual; in the second category, the homosexuality is less prominent. In the first group, the life style is homosexual. Social relationships and meaningful emotional relationships are had with other homosexuals, with the possible exception of members of the family and in some instances carefully selected heterosexual friends. The other group live in the heterosexual world. They are usually married, have children, and seem, on the face of things, to conform to heterosexual standards. They carry out their homosexual activities in the greatest secrecy, unknown to those closest to them. Few, if any, are recognizable as homosexual. Many in the first group do not conform to the popular effeminate stereotype. They themselves are largely of the opinion that they can distinguish

each other. This may involve a cue and response signaling system. For obvious reasons, few homosexuals are unconcerned about being exposed, and most successfully conceal their condition.

The homosexual world. Homosexuals tend to gravitate toward large urban centers where, in more recent times in this country, they have built up a social system that has the features of a subculture within the larger society. There are both visible and hidden areas in the homosexual world. Turkish baths, well defined sections in cities, and resort spots are part of the visible world that is habitually frequented by homosexuals who have openly affiliated themselves with this life style. Others move in and out of it, and still others hold it in contempt and avoid it.

Homosexual society is stratified. A small elite with money, power, and prestige make no contact with the visible homosexual world but are known to it. As occurs in an open class system, many homosexuals are upwardly mobile and aspire to be accepted by the "in" group. The elite is cliquish, and they behave like most socially select groups. To give voice to their aspirations and needs, visibly committed homosexuals of both sexes have formed national organizations. They attempt to improve the public image of homosexuals, to protect them from persecution and discrimination, and to give them a sense of personal dignity; but they are not oriented toward helping their members change their pathological sexual pattern.

Homosexuals who seek to affiliate themselves with the homosexual world hope to find fulfillment of social, emotional, romantic, and sexual needs. The sought fulfillment consists of living happily with a homosexual mate in an analogue of heterosexual marriage. Few, if any, realize this wish. As youths, many fall passionately in love, only to have their romances break up somehow after relatively short periods of time. These liaisons run a stereotypic course. Passionate beginnings are followed by episodic phases of turbulence and fade into ennui before ending. By maturity, they have long since abandoned the hope of finding romantic satisfaction in a homosexual relationship. If a homosexual continues to be a member of a pairing, he learns to expect far less than bliss or even reasonable contentment. The few relationships that endure tend to be characterized by sharp conflict or by absence of sexual activity, so that sexual gratification may be sought outside the partnership. Such extra-pairing liaisons are casual and emotionally shallow and may be anonymous to the point of mutual ignorance of identity.

The unattached homosexual is, by and large, a lonely hunter, seeking sexual satisfaction where he can find it. The chronic frustration of romantic longings spurs him into the restless displacement behavior common to most homosexuals, which they express in a frenetic pursuit of excitement and pleasure

epitomized in the phrase "the gay life." The average heterosexual spends far less time and energy in sexual pursuits than do homosexuals, especially those who perpetually involve themselves in nocturnal prowling for new partners—cruising streets, bars, and haunts known to be frequented by other homophiles. These encounters expose them to a variety of dangers: robbery, beatings, blackmail, and venereal disease. The incidence of gonorrhea and syphilis has sharply increased of recent years, much of it traceable to homosexuals. When treating the homosexual patient, the physician must be alert to the possibility of venereal disease.

The homosexual encounters of bisexuals who are predominantly heterosexual occur episodically for the most part. The homosexual activity may be a compulsive outburst; it may occur during periods of stress or while under the influence of alcohol or when away from home on business or vacation. The homosexual world has dubbed such men "closet queens" because of the secrecy with which their homosexual activities are pursued. Psychiatric examinations reveal these men to be sexually inadequate as husbands or unable to sustain effective emotional contact with their wives. These bisexuals are circumspect about homosexual activities, but in some instances they seem to invite apprehension by the authorities and subsequent public exposure. A small number renounce heterosexuality and become committed homosexuals.

Sexual practices. Homosexuals are more preoccupied with sex than are heterosexuals; they begin sexual practices earlier and are more often sexually active in preadolescence, adolescence, and adulthood. In a systematic study of male homosexuals by this author and associates, 35 per cent of the sample were already aware of their sexual interest in males by the time they were 10 years old; about 80 per cent had this awareness by the age of 16; less than 10 per cent became aware of their inversion after the age of 20. Of the 106 homosexuals studied, 60 per cent remembered having had erotic responses to another male by the age of 12. By the age of 14, more than half had participated in homosexual activity involving genital contact, compared to less than 10 per cent of the comparison group of heterosexuals who by the same age had had a genital heterosexual experience.

Most commonly, homosexual practices involve kissing—including tongue play—caressing, and mutual masturbation. The mouth and anus as sexual orifices usually become part of the pattern as homosexuals gain in sexual experience. Among the patients studied, one third had engaged in sexual activity involving orifices by the age of 16. The others tended to enter into these practices as they grew older.

For accuracy of description, where fellatio is practiced, the individual being sucked may be designated as the insertor, the partner as the insertee. The insertor may remain relatively passive while the in-

sertee is actively sucking, or the insertor may actively simulate intercourse. The partner's mouth is then equated with the vagina. In anal intercourse—also referred to as pederasty, sodomy, and buggery—the insertor is active; the insertee is passive. Many homosexuals have a habitual and preferential sexual practice, but the majority vary their techniques; they may take different roles at different times with different partners. Most homosexuals have certain strong disinclinations; for example, a man may be an insertor in anal activity, but find the role of anal insertee repulsive. Some are interested in oral practices only; others in anal activities only. There is no reliable correlation between appearance, social behavior, and preferred sexual practices. Masculine types may be exclusive oral insertees or anal insertees, and more effeminate homosexuals may be exclusive insertors.

The most popular choice of homosexual partner is the masculine type or the male who has traits that symbolize masculinity. A large penis is highly valued and sought as the ultimate in masculine symbolism. Emphasis is also placed on beauty of figure and muscular development. Only a minority of homosexuals *consciously* look for feminine characteristics in the partner. Some in this category seek transvestites as partners who, when wearing feminine clothing, are said to be "in drag." The seeking of children as sexual partners is rare among those who are exclusively homosexual. Pedophilia occurs mostly among bisexuals. As a group, such bisexuals tend to be older men who may even be married and have children.

Despite an apparent disinterest in and aversion to heterosexual intercourse, evidence of sexual responsiveness to women can be demonstrated in most homosexuals, including those who are exclusively homosexual. Of the group systematically studied, two thirds had made an attempt at heterosexual intercourse, and of these about one half had been successful. In the course of psychoanalytic treatment, half the number who were exclusively homosexual had presented dreams depicting explicit heterosexual strivings. One repeatedly observes clinically that they seek feminine companionship and tend to become depressed when separated from women for any prolonged period. Homosexual couples often make friends and companions of a female homosexual pair. If the heterosexual threat is neutralized by a woman's sexual unavailability because of marriage, advanced age, etc., homosexual men may be affectionate, charming, and even subtly seductive.

Etiology

Pre-Freudian theories. The pre-Freudian conceptualizations about the etiology of homosexuality were based on two major and related assumptions: (1) There is a universal bisexuality. (2) There is a congenital or hereditary basis for the accentuation of

the feminine component among male homosexuals. Ellis summarized the bisexual assumption:

We thus see that the ancient medico-philosophic conception of organic bisexuality put forth by the Greeks as the key to the explanation of sexual inversion, after sinking out of sight for 2,000 years, was revived early in the 19th century by two amateur philosophers who were themselves inverted (Hügel, Ulrichs) as well as by a genuine philosopher who was not inverted (Schopenhauer). Then the conception of latent bisexuality independently of homosexuality was developed from the purely scientific side (by Darwin and evolutionists generally). In the next stage this conception was adopted by the psychiatric and other scientific authorities.

The pre-Freudian psychiatrists were in agreement that an inherited predisposition was basic in the etiology. Some allowed that experiential factors might be influential when the inherited tendency was not strong. The condition was conceptualized by some authors as abnormal but not necessarily as a disease such as color blindness, to which it was compared. Krafft-Ebing, among others, viewed it as a stigma of degenerative disease of the nervous system, though later he committed himself to the bisexual assumption. Ellis considered male homosexuality to be a biological variant in the sense of a mutation. All considered the condition to be untreatable, though Krafft-Ebing did attempt to activate heterosexuality in his patients by the use of hypnosis.

Deviant but normal theories. The nature or nurture controversy is still a live issue as concerns etiology, though there are attempts to integrate or work out variations of these opposing approaches. Some workers hold that homosexuality is a sexual deviation along a spectrum of widely varied sexual behaviors, all falling within a biologically normal range. The concept that homosexuality is deviant but normal is essentially statistical, in the sense that genius and low normal intelligence are deviations from the statistical norm of average. It is based on the assumption that innately man is neither heterosexual nor homosexual; the path his sexual development takes depends on the particular way he has been conditioned and biosocially patterned. Accordingly, homosexuality is considered to be pathological only in societies having taboos and prohibitions against it.

As one order of supporting data, these proponents cite sexual behavior between same sex participants in infrahuman species, particularly the mounting behavior of estrous females who mount other females and males who mount other males. The meaning of such behavior, however, is not well understood. We have no information as to the steering mechanisms or cues that set it off. Classing it as homosexual implies that the animal is seeking and attaining homosexual gratification as we know it to occur in humans. Even where there are copulatory attempts, as in thrusting movements, nothing is known about the arousal stimuli. Is the arousal a response to internal or external stimuli? Does it occur when estrous females are in the vicinity but are unavailable for reasons unknown

to the human observer? There are countless other questions one could raise.

The salient fact about animal sexual behavior that is rarely mentioned is that in no other species where reproduction depends on male-female coupling have deviant types appeared that fear or abhor heterosexual mating and engage solely in homosexual behavior consistently, exclusively, and in highly organized sociosexual patterns. In humans the presence of anxiety and fear of heterosexuality is a central feature of the inversion. This has no counterpart among infrahuman species. Taken by itself, this fact is reason enough why animal behavior is not suitable as a model for interpreting human homosexuality, though it may offer some clues that might be suggestive—for example, the presenting behavior seen among male monkeys following a threat by a more aggressive male. But it is a giant step to draw a one-to-one analogy between this relatively simple behavioral sequence and the complexity of psychodynamic mechanisms, motives, and behaviors operant among humans.

A second order of evidence used to buttress the deviant but normal hypothesis deals with conditioning or early imprinting. It rests on the assumption that sexual object choice is learned or conditioned and excludes the possibility that biological steering mechanisms direct the male to the female or vice versa. The work of Money and the Hampsons on hermaphroditism has often been cited as evidence supporting the conditioning hypothesis. These workers have shown that gender role and sexual orientation and direction correlate with parental sex assignment and that gonadal, hormonal, and chromosomal statuses are not the crucial determinants in the gender role behavior of hermaphrodites. These authors have made a valuable contribution toward understanding the psychological development of hermaphrodites, but this work has no direct application to homosexuality. Gender role assignment is based on anatomy, and, since homosexuals are anatomically normal, male gender role is assigned at birth. Homosexuals know full well that they are males. They do not shift into states of mind during which they believe they are women because of role confusion or faulty self-image. They do, however, suffer from doubts and feelings of insecurity about their maleness. Masculinity is a sociocultural construct referring to a male's capacity to fulfill expected role behavior. It includes the ability to attract females and to function sexually with them. Many homosexuals have profound anxiety about appearing masculine, and some conceal such evidence behind a facade of effeminacy.

In this writer's view, biological steering mechanisms probably exist that ensure the heterosexual direction of object choice. One such steering mechanism may be olfactory, in man as in infrahuman species. Militating against a conditioning assumption is the erotic heterosexual content that appears in the

dreams of homosexuals. Such dreams usually contain symbols of threat and are accompanied by anxiety. If a homosexual were truly conditioned, he would have neither a heterosexual response nor an anxious or aversive reaction to females; he would be neutral and nonresponsive.

A third order of evidence used to support the deviance hypothesis consists of historical and cross-cultural data on the widespread occurrence of male homosexuality in ancient as well as modern civilization. Some authors indicate, explicitly or implicitly, that homosexuality would be ubiquitous were it not tabooed. According to Kinsey et al.,

Whatever factors are considered, it must not be forgotten that the basic phenomenon to be explained is an individual's preference for one sex, or for a partner of the other sex, or his acceptance of the partner of either sex. This problem is after all, part of a broader problem of choices in general; the choice of the road one takes, of the clothes one wears, of the food that one eats, of the place in which one sleeps, and of the endless other things one is choosing. A choice of partner in sexual relations becomes more significant only because society demands that there be a particular choice in this matter, and does not often dictate one's choice of food or of clothing.

Yet there are societies where male homosexuality has not been observed and where it appears to be absent entirely. Citing his personal anthropological experiences, Marvin K. Opler, a social psychologist, stated, "In field work among Ute Indians of Colorado, this author's checks on such topics [homosexuality] yielded amusement, disbelief, and counter-questioning on American urban culture." Ralph B. Jacoby, a psychoanalyst who has interviewed Vyana Indians in Surinam, stated in a personal communication that these people have no concept of male homosexuality, no word for, no observable prohibition and that his inquiries about homosexuality evoked perplexed amusement. Thoden Von Valsen, an anthropologist who in recent years lived for 18 months with the Bush Negroes (Djukas) of Surinam, observed no evidence of homosexual behavior among them. T. A. Lambo, chairman and professor of psychiatry at the University of Ibadan, Nigeria, informally reported that, as far as he is aware, in the tribal organization that constitutes approximately 80 per cent of Nigeria's 53 millions, there is no male homosexuality or any prohibitions against it. In Israel, male homosexuality is extremely rare among those raised on the kibbutzim.

A fourth order of evidence is based on Hooker's work with projective techniques. Rorschach and Thematic Apperception Tests were administered to a group of homosexuals and heterosexuals and were then interpreted by three judges, authorities on projective testing. Hooker reported:

The most striking finding of the three judges who examined the projective materials was that many of the homosexuals were very well adjusted. In fact, the three judges agreed on two thirds of the group as being average or superior in adjustment. Not only do all homosexuals not have strong feminine

identifications nor are they all 'somewhat paranoid' but according to the judges some may not be characterized by any demonstrable pathology (Marmor).

However, the test findings reported are not in accord with clinical experience. In this regard, criticism is often leveled at clinicians, who are supposedly biased by skewed samples of homosexuals who have psychiatric problems. This writer had the opportunity during World War II to examine psychiatrically 50 homosexuals who had been apprehended by the military police. These soldiers were not patients, nor did they regard themselves as such, but they manifested easily discernible psychopathology quite similar to that seen among homosexuals who enter treatment. Neither Hooker nor the judges defined what they considered to be "well adjusted." At best, the term refers to a purportedly well functioning individual without gross visible symptoms. It does not preclude the presence of severe underlying psychopathology. Beyond Rorschach testing, a larger sample of apparently well adjusted homosexuals should be clinically screened by psychoanalysts. Such a study might well reveal constellations of psychopathology related to the homosexual adaptation.

Genetic theories. Contrasted to the workers who consider homosexuality to be a deviant but not aberrant condition are those who view homosexuality as a constitutionally or genetically determined disease, disorder, or defect. The strongest support for this argument derives from Kallmann's twin studies. Kallmann studied 85 pairs of homosexual twins, 45 of whom were dizygotic and 40 monozygotic. He reported that the concordance rates of homosexuality (the percentage of pairs in which both members were homosexual) were somewhat higher among dizygotic twins than that reported for the total male population, considering only Groups 5 and 6 on the Kinsey scale, but not differentiated at a statistically significant level. For the monozygotic twin pairs, however, Kallmann reported 100 per cent concordance.

These statistics are indeed impressive, but they must be interpreted with caution. The fact that monozygotic twins are genetically similar does not mean that if they develop similar complex patterns of behavior, these patterns are, therefore, genetically determined. The possibility that each twin is exposed to similar social influences must be considered, as should the individuated identification processes. In Kolb's study of seven monozygotic twin pairs, one member of each pair was homosexual and the other heterosexual. This study did not support Kallmann's astounding findings of 100 per cent concordance.

Freud's theories. Freud's conceptualizations about the etiology of male homosexuality combined biogenetic and psychosocial hypotheses. He accepted the bisexual theory of his day but put his own stamp on it. Constitutional factors were thought to explain preponderant tendencies toward or away from activity. Masculinity was identified with activity; fem-

inity was identified with passivity. Constitutional factors were also invoked to explain exaggerated influences of the oral and anal zones, which, in their receptive aspects, were identified with femininity and, in their sadistic aspects, with masculinity.

Freud allowed that life experience could play a determining role in extinguishing or reinforcing genetic factors; that is, experience could play its part in establishing pregenital libidinal fixation. He never explicitly assigned quantitative values to the dual genetic and psychic determinants but implied that they might vary in each case. Thus, he left room for homosexuality as a pathological condition resulting from abnormal experience within the family. He described homosexuals as having had an intense erotic attachment to their mother during childhood "which was evoked and encouraged by too much tenderness on the part of the mother herself and further reinforced by the small part played by the father."

Freud predicted that his bisexual theory would eventually be confirmed or invalidated by biological advances. Since his time, it has been determined that in the normal organism bisexuality is a fiction. Physical, chromosomal, and hormonal examinations reveal homosexuals to be biologically normal males. Sex is clearly differentiated at the moment of conception by the XX and XY chromosomal pattern, and there is no biological basis for assigning bisexual constitutional components. The bisexual theory as a set of conceptualizations to explain the etiology of male homosexuality is no longer tenable, nor is there any existing evidence to support a genetic theory of homosexuality.

Rado, the first psychoanalyst to review Freud's bisexual theory critically, had this to say:

There is no such thing as bisexuality either in man or in any other of the higher vertebrates. In the final shaping of the normal individual the double embryological origin of the genital system does not result in any physiological duality of reproductive functioning. This double origin is of significance only in developmental disturbances and reversals resulting in an admixture of structural characteristics of the opposite sex and thus recognizable as inconsistencies of sex differentiation. In such abnormally built individuals reproductive activity may be impaired or impossible, but the presence in their genital structure of fragments of the opposite sex does not confer on them the reproductive capacity of that sex (Marmor).

Experiential theories. The findings of a comprehensive, long term study by Bieber et al. demonstrated the association between adverse intrafamilial influences and homosexual development, thus strongly supporting the theory that homosexuality evolves as a consequence of deleterious experience. In comparing 106 male homosexuals in psychoanalytic treatment with 100 heterosexuals in treatment, certain clusters and themes of parental attitudes and behavior were found to be typically characteristic of the homosexual case histories. Significant statistical differences were found between the homosexual and heterosexual pa-

tients, particularly in items tapping parental interaction and influence.

The modal type of mother of the homosexual was overly close, overly intimate, possessive, and dominating; she was overprotective as well as demasculinizing. She spent a great deal of time with her son and generally favored him from childhood on over other siblings. She demanded undue attention and solicitude from this boy. She encouraged an alliance against the father and frequently openly preferred son to husband. Puritanical and sexually frigid, she interfered with her son's heterosexual interests in childhood and adolescence, yet she herself tended to be seductive with him. Overly concerned about illness and physical injury, she babied him and hindered his participation in normal activities and the rough and tumble of boyhood, presumably out of concern for his welfare. In a few cases, the mother was seemingly detached, rejecting, and overtly hostile, but the majority had formed a possessive, controlling, inappropriately intimate relationship with the son. There were instances where mother and son occupied the same bed far into the boy's adolescence or where the mother exhibitionistically exposed her nudity.

Salient attitudes to such a mother included submissiveness, overeagerness to please her, and a fear of displeasing or hurting her. These sons usually felt admired and accepted by the mother; in turn, they admired and respected her. Consciously, few homosexuals hated or feared their mother; they turned to her for protection and sided with her in family quarrels.

The father was usually detached, unaffectionate, and hostile to this son, whom he minimized and humiliated and with whom, in most cases, he spent very little time. Rarely his father's favorite, usually his least favored child and scapegoat, in the large majority of cases the homosexual hated and feared his father and lacked respect or admiration for him.

Thus, the parental constellation most likely to produce a homosexual or a heterosexual with severe homosexual problems was a detached, hostile father and a close-binding, overly intimate, seductive mother who dominated and minimized her husband.

The majority of patients described their parents as conforming to these profiles. There were exceptions. Some of the mothers were apparently detached, disinterested, and even explicitly hostile. They constituted a small group whose maternal neglect and underprotectiveness resulted in their son's exposure to a variety of traumatic experiences beyond the adaptive capacity of children. Some of the fathers were overly close but were, nevertheless, minimizing and demeaning. Not one father of a homosexual in this study was classified as a warmly related, constructive parent; in the heterosexual sample the father-son relationship was much more positive. It was concluded that a male child would not become homosexual if he had a loving father, despite the influ-

ence of a mother who conformed to the profile of the homosexually inductive mother. In many cases both parents were able to relate more normally to their other sons.

Extensive clinical and research findings permit the following formulation. Despite differences and variations in neurotic motivation, homosexually inductive parents quite specifically direct themselves toward inhibiting in the child manifestations of assertive masculine behavior; there are unconscious but unremitting attempts to extinguish the son's heterosexuality. Evidences of heterosexual interest and clearly masculine role behavior evoke in such parents anxiety and suppressive behavior that is effectively castrating.

In communicating a desire for singular and unusual closeness to her son, the homosexually inductive mother articulates her pathological behavior with the child's natural need for maternal warmth and closeness. Between the 3rd and 4th year of life, the wish for close contact with the mother strongly reinforces the developing capacity for heterosexual responsiveness that ushers in the Oedipus complex. At the same time, the mother has led her son to believe that he has a basis in reality for expecting gratification of wishes for exclusive rights, privileges, and possession of her.

The adhesive tie between mother and son promotes intensely rivalrous and murderous feelings in the boy toward the father. Fear of retaliation gives rise to irrational fears of the father. Most homosexual patients have had fathers who responded to the oedipal phase by acting out hostility or expressing it through seeming disinterest and lack of involvement while covertly expressing contempt or anger. A mutually competitive struggle between a young child and an adult thus unfolds. Clearly, the winning odds are stacked against the child, who finds himself in the frightening situation of facing an opponent recognized as potentially overwhelming. The boy not only is deprived of realistic needs for paternal security and protection but is denied an admired, loved figure for masculine identification. Where a father adequately fulfills the paternal role—that is, by meeting the realistic dependency needs of his son and encouraging a masculine identification—the sexually determined competition is then neutralized or counteracted. The frustration of a son's need for his father intensifies filial hostility and promotes even further pathological dependency on the mother; at the same time, a yearning for paternal love endures.

A morbid resolution of the Oedipus complex is determined by both the father and the mother in a situation where the son is overly attached to his mother and intensely hostile to his father. The dynamics of this triangular interaction illuminates the problem of the homosexual's persisting affectional tie to his exploitative, dominating, castrating mother and his enduring hatred and fear of a sexually de-

structive father, even when the paternal figure has been consciously viewed as weak and inadequate. From the beginning of the oedipal phase and thereafter, sexual responses, attitudes, and behavior play a determining role in interpersonal relationships and are themselves influenced by all the other dynamic interactional processes operant in human relationships. As biosocial development proceeds, sexuality directs the male toward the female, but in the development of the homosexual, fears of heterosexuality inhibit him in his relationship with girls. At the same time, conflictual attitudes toward other males are set off—dependency on the one hand, competitiveness and hostility on the other.

Entrapment by seduction into homosexuality by other homosexuals, particularly older men, has been popularly held to be an important etiological factor. Clinical findings do not support this supposition. There is no evidence that seduction by other homosexuals is of any significance. Doshay reported a follow-up study of a series of 108 boys who had been sexually seduced between the ages of 7 and 16, and none subsequently became homosexual.

Motivational factors. Closely related to etiological conceptualizations are the psychodynamic formulations that relate to the order of motivational factors governing homosexual development and behavior. Freud believed that the sexual practices in homosexual relationships symbolized regressions to fixation points in libidinal development. The homosexual supposedly sought someone like himself—someone with a penis—as love object, thus confirming the view that the invert regressed to the earliest libidinal level, the narcissistic or autocrotic phase. In an attempt to recapitulate the mother-child relationship, the homosexual chooses a narcissistic object to love. Fixations on the oral and anal level based on the fear of loss of the breast and feces provide the libidinal precursors of castration anxiety and predispose to an excessive fear of phallic loss. Consequently, according to this schema, there is an overevaluation of the penis and an avoidance of females, since they lack it. At the phallic and related oedipal level of development, castration fear, arising from expectations of retaliation for having castration wishes toward the father, provides the basis for a retreat from a masculine posture and favors an identification with the mother and feminine orientation to the feared father.

Freud's theoretical formulations were oriented to the child's psychology in the context of the libido theory. Minimal emphasis was placed on parental psychopathology as it interdigitates with the child's maturational phases. Melanie Klein placed special emphasis on the oral phase. According to her formulation, oral frustration in the infant results in cannibalistic fantasies of the mother's breast and total person. The projection of such fantasies gives rise to fear of being devoured. The vagina is unconsciously equated with the mouth; homosexuals learn to avoid

those who possess this dangerous organ, and they direct themselves instead to males.

New concepts were introduced by psychoanalysts whose theories were rooted in other conceptual systems. Sullivan emphasized the homosexual's difficulty in achieving a close relationship with members of either sex. During preadolescence and early adolescence, homosexuals' interpersonal problems interfere with adequate peer group relationships with males; because of heterosexual fears, they cannot seek close ties with girls. Isolation and alienation thus become central problems. In Horney's view the motivational mechanisms of homosexual relationships and behavior are basically nonsexual. These motives consist of needs to dominate and subdue, intense and irrational needs to please others, and needs to avoid competition with peers in order to escape injury to neurotic pride. Thompson viewed homosexuality as but one symptomatic manifestation of the broader problem of disturbed interpersonal relationships. She agreed with Freud that all people were potentially polysexual and, therefore, one's ultimate sexual adaptation depended on whether heterosexual or homosexual patterns provided the better basis for optimal relatedness.

Rado identified several types of homosexuals: (1) Heterosexuals who are situational homosexuals; they indulge in homosexual behavior because females are unavailable, as occurs in prisons. (2) Incidental homosexuals, who indulge in homosexual behavior sporadically, as may occur during preadolescence and adolescence. Their behavior does not reflect a basic homosexual character structure. (3) Homosexuals who are disorganized schizophrenics; the homosexuality is an expression of chaotic behavior. (4) Surplus variation—an expression of sexual curiosity and wishes for diverse sexual experience. (5) Reparative homosexuality—present in most exclusively or predominantly homosexual males. According to Rado, reparative homosexuality is based on "hidden but incapacitating fears of the opposite sex which result in a homosexual adaptation, which through symbolic processes is in fantasy a heterosexual one, or in which problems of rivalry with isophilic partners who represent father are solved."

Ovesey introduced the concept of pseudohomosexuality—a condition seen in heterosexuals obsessively preoccupied with the idea that they are homosexual. The psychodynamic variables underlying pseudohomosexuality are considered to be pathological dependency and inhibited assertiveness. According to this construct, the patient equates inhibited assertiveness with castration and, therefore, with femininity and homosexuality. True homosexuality is seen to contain these dynamic mechanisms but, in addition, is characterized by a capability for erotic arousal by other males. In etiology, true homosexuality is assigned to excessive sexual discipline.

Proposed theory. This writer's views of male

homosexuality are more in accord with Rado than with other workers, differing in ways that will be elaborated. Male homosexuality is primarily a disorder of sexual development in individuals toward whom highly pathological parental attitudes and behavior have been directed. Classical Freudian theory postulates that object-related sexuality begins at birth. One of the initial phases is termed "oral" and involves infant and mother interactions. There is no evidence, however, that these interactional processes are sexual at this period, though they are of great importance in the formation of personality and in psychopathology. Apart from infantile masturbation, observed especially in males during the 1st year of life, the responses to object-related sexuality start with the onset of the Oedipus complex. Initial heterosexual responsiveness is characterized by a beginning interest and excitement toward members of the opposite sex. In males, differentiated interest first centers on the mother or mother surrogate; in females, on the father or father surrogate. This developmental phase begins between the 2nd and 4th years of life. Reports by Bieber and Kalagerakis are highly suggestive that olfaction plays a determining role in the early differentiated reaction to heterosexual objects.

From birth on the child participates in complex developmental events in which the parents are cardinal figures. Their attitudes and behavior profoundly influence the child's evolving personality and significantly determine the ways in which he will meet and integrate new phases. Parental attitudes and behavior are not static. A child's maturational changes evoke new parental behaviors—appropriate in normal parents, pathological in neurotic parents. Thus, the oedipal phase initiated by biological change articulates with preexisting personality organization in both parent and child.

At about the time a child's heterosexual interests and responses become apparent, same sex rivalry, perhaps a concomitant of heterosexual orientation, also becomes discernible. A boy's rivalry is directed predominantly toward his father but may include other males perceived as competitors for valued females. In girls, rivalry is directed toward the mother and other females. Whether rivalrous reactions are biologically determined, as are heterosexual responses, remains a question. Same sex rivalry is ubiquitous in many mammalian species.

The Oedipus complex as described by Freud consists essentially of a constellation of sexual orientation to the mother and rivalry to the father. The boy's rivalry may coexist with feelings of love, admiration, and hero worship. Whether competitiveness will be reinforced or neutralized is determined by a multiplicity of events and influences but particularly by the relationship with the father. A constructive, warmly related father who is not competitive with his son, more especially not *sexually* competitive, seems to be an essential factor in the child's ade-

quate mastery of feelings of rivalry and in his ability to cope with antagonistic behavior from other males. As has been emphasized by Sullivan, peer group relatedness in childhood and adolescence provides the opportunity for the establishment and reinforcement of affectional and cooperative attitudes among males; it is the testing ground for competitive and combative behaviors and for learning that one survives in the face of aggression. Ethologists have contributed provocative material for conceptualizing problems in this area. Tinbergen has studied combative attitudes and behavior between same sex members of avian species. He points up the survival value of agonistic posturing in birds that contain behavioral components of flight and fight. These postures constitute a communication pattern that usually obviates combat. Much has still to be learned about antagonistic behavior in humans.

In the psychoanalytic treatment of male homosexuals, the fear most centrally related to the avoidance of heterosexual involvement is attack from a male competitor. The homosexual anticipates the attack as primarily physical and murderous and secondarily as a threat of rejection by significant males. His overwhelming fear of attack directs him away from heterosexual desires and toward habitual homosexuality. This adaptation is established in preadolescence or adolescence by eroticizing objects and attributes he most fears—aggressive males and masculine strength. Masculine strength and power are symbolized by the large penis, physical size, prowess, and other characteristics associated with masculine power, such as money, prestige, intellectuality, and so forth. Some homosexuals tend to abstract characteristics of meaningful females to whom they unconsciously respond erotically; they seek these qualities in males, whom they then find sexually arousing. Such abstractions may involve hair, eye, and skin color or facial and characterological elements.

In the homosexual act, as in the established homosexual relationship, a variety of needs are acted out. These needs include human contact and relatedness, sexual gratification, attempts to rehabilitate a sense of damaged masculinity and heterosexuality, and attempts to release inhibitions of function in performance, such as work involving competition with other males. The homosexual act is not an analogue of heterosexual intercourse. It is, in part, a heterosexual masquerade in which multiple role behaviors are enacted. In anal intercourse the roles are well defined. The insertor is masculine; the insertee is feminine. The anus is equated with the vagina by both partners. Similar role behaviors imitative of heterosexuality may be acted out in oral activity, where the insertor may become the masculine partner and the insertee the feminine partner. Another parameter includes the representation of power through dominance in the masculine role and submission in the feminine, receptive role.

The condensation of symbolic heterosexual and symbolic defensive and reparative mechanisms expressed in the homosexual act are also represented in the interpersonal transactions of the more permanent relationships. Supermasculine partners may be sought to work through unresolved problems had with the father or to bulwark or repair self-esteem and defects in functioning. A partner may be chosen who is believed to be the kind of man the father would have wanted as a son. Or, as pointed out, a partner may be sought who possesses a physical attribute associated with the mother or a sister; incestuous feelings may be covertly expressed behind a homosexual mask. Members of homosexual pairings are often intensely jealous of their lovers; in fact, the jealousy is more intense than one generally sees in heterosexual pairs. Dissolution of a homosexual relationship may lead a partner who feels rejected and abandoned to act out grossly destructive behavior, occasionally even murder. Jealousy is but one manifestation of mistrust of the partner. It derives from fears of being exploited, treated inconsiderately, dominated, humiliated, and disappointed in the fulfillment of a range of unrealistic wishes rooted in pathological dependency. Suspicion and fear, in large part, determine the turbulence and brief duration of homosexual relationships.

Latent homosexuality. According to classical psychoanalytic theory, human sexual instinct contains a homosexual component—for example, there is a universal homoeroticism. The theory holds that normal adult males repress or partially sublimate this component in affectionate relationships with each other. Abraham stated:

In normal individuals the homosexual component of the sexual instinct undergoes sublimation. Between men feelings of unity and friendship become divested of all sexuality. The man of normal feelings is repelled by any physical contact implying tenderness with another of his own sex.... Alcohol suspends these feelings. When they are drinking, men will fall upon one another's necks and kiss each other.... When sober, the same men will term such conduct effeminate.... The homosexual components which have been repressed and sublimated by the influence of education become unmistakably evident when under the influence of alcohol (Marmor).

Many psychoanalysts do not assume a universal latent homosexuality. Among 41 per cent of the heterosexual sample in the study for the book *Homosexuality—A Psychoanalytic Study*, evidence of latent homosexuality was absent. This finding failed to support the classical psychoanalytic position. Many heterosexual patients, however, report one or more of the following symptoms: fears about becoming homosexual; fantasies of homosexual activity; impulses to perform homosexual acts; compulsions to look at men's genital areas; dreams with homosexual content; reactions of fear and disgust toward homosexuals; anxiety and feelings of uneasiness when in the presence of homosexuals; homosexual episodes in childhood and adolescence; and desires to be a woman. The symptoms are usually a source of dis-

tress to patients and their meaning a source of interest to psychiatrists.

Homosexual symptoms or, as more recently termed, "homosexual trends" share etiological features with the entrenched mechanisms of homosexuals. Fear of competition and attack is a central dynamic of homosexuality. These fears may be set off in situations threatening competition with other males, such as falling in love, marrying, and achieving success. Guilt-ridden fear that individual achievement of one sort or another will exclude and deprive other males, who will then aggressively retaliate, leads toward submissive renunciation of a desirable heterosexual love object or other goals. Hand in hand with renunciation go wishes for reward and compensation for the sacrifice. A tendency to enter into a pathologically dependent relationship with a powerful male figure is accompanied by the hope that he will grant a substitute for the renounced gratification. This mechanism is clearly operative in the overt homosexual who gives up desired heterosexuality and then seeks substitutive gratification in homosexual activities.

The single most prominent feature distinguishing overt homosexuals from heterosexuals with homosexual trends is the absence among the latter of erotic responsivity to males. Erotic responsivity to males is usually established during the childhood or adolescence of homosexuals. Heterosexuals with homosexual trends rarely become involved in homosexuality. Men who become involved repetitively—be it in prisons, during periods of absence from women, out of curiosity presumably, or for "kicks"—are bisexuals who from time to time shift to overt homosexuality when under psychological stress. Heterosexuals do not become homosexual when separated from females. In World War II, millions of men were separated from women; some for months, even years. Practically none engaged in homosexual activity who had not already done so in the past.

Treatment of patients with homosexual trends involves helping them to resolve irrational fears of male competition and delineating those experiences in life that gave rise to the fears.

Treatment

Prophylaxis. The two major approaches to the prevention of homosexuality are early detection of homosexual tendencies and public education.

Most prehomosexual children exhibit characteristic problems and behavior. They tend to be inordinately fearful of physical injury; they are apt to avoid the scrambles and bruises in games of normal boys. The prehomosexual is usually an isolate who does not become a member of a peer group. He tends to avoid competitive sports and is frequently disinterested in athletics. A minority have effeminate gestures and attitudes. Such boys are the ones other children recognize as different. They are called "sissies" and are

made the butt of peer group hostility. When a child presents such a picture, a psychiatric examination is indicated. If the psychiatrist is able to identify a prehomosexual problem, psychotherapy is indicated for the child and his parents. Early treatment may resolve the underlying problems, enough at least to prevent the consolidation of a homosexual adaptation.

Adolescence is a crucial period, especially for those who have serious sexual problems. Although homosexual patterns are organized during preadolescence, they do not usually congeal into a coherent system until adolescence. If a prehomosexual adolescent can be detected and treated before homosexual activity is attempted, prognosis for recovery is far more optimistic than if he is treated later. Adolescents who consciously avoid girls, who do not develop a crush on a girl, or who may already sense in themselves homosexual tendencies are candidates for psychiatric examination, as are the parents of such boys.

The main targets for a prophylactic educational program are parents, the clergy, physicians, and educators. They are in a position to detect early homosexual manifestations and to guide young people into corrective, therapeutic channels. Teachers, in particular, are sensitively placed, since they spend the greater part of a child's day with him. Mental health facilities in schools, including walk-in clinics for parents, would be a convenient and appropriate setting for discussing problems with qualified personnel.

Reconstructive therapy. Homosexuality can be treated successfully, and the rate of reversal is considerably higher in recent times than formerly, when psychiatrists were imbued with gloomy prognostications about this condition. In the *Homosexuality* study, 29 of 106 male homosexuals had become exclusively heterosexual. Of these 29 cases, 14 had been exclusively homosexual, and 15 had been bisexual at the start of treatment. Of the initial 106 homosexuals in the total sample, 76 had been exclusively inverted at the outset of treatment, but only 43 remained so as of June, 1960. In a follow-up study in June, 1965, it was found that 15 of the 29 cases who were exclusively heterosexual as of June, 1960, had maintained contact with their psychoanalyst. Of these 15 cases, 12 had remained exclusively heterosexual; the other three cases remained predominantly heterosexual, with sporadic homosexual episodes under situations of stress. Thus, approximately 30 per cent of homosexuals in this study became and remained heterosexual.

In 1965 Mayerson and Lief reported a follow-up study of 19 homosexual patients who had undergone psychotherapy. The mean duration of therapy was 1.7 years, and the mean interval between the end of therapy and follow-up was 4.5 years. "In the overall evaluation at the time of follow-up, 46.3 per cent of the patients were found to be 'apparently recovered' or 'much improved,' and 26.3 per cent were im-

proved in comparison to their status at the beginning of therapy. In the majority of patients the follow-up revealed progress in all behavioral areas since the end of treatment" (Marmor).

Recommendations for treatment are determined by how the physician conceptualizes homosexuality and how he views prognosis for change. If homosexuality is viewed as a deviance within a range of biologically normal behavior, like left-handedness, then therapy will be deemed to be unnecessary unless other debilitating psychiatric symptoms require attention. But if homosexuality is viewed as pathological, treatment will be recommended, provided there is a reasonable possibility for change. The results of treatment as reported by the studies cited, and others, establish the efficacy of therapy.

What are the indications for therapy, and what types of therapy are indicated? Youth is an important factor. Homosexuals under 30 and all homosexual adolescents should be advised to undergo psychiatric treatment. This is not to say that homosexuals over 30 should not be treated; many have had a successful psychotherapeutic outcome. However, the longer a homosexual has been involved in and committed to a homosexual way of life, the lower the probability for shifting to heterosexuality. Bisexuals, particularly those who are predominantly heterosexual, should also be encouraged to enter treatment.

The *Homosexuality* study delineated a series of factors indicative of favorable prognosis: (1) a wish to change verbalized at the outset of treatment; (2) respect and admiration for one's father; (3) beginning treatment before the age of 35; (4) a history of having attempted heterosexual intercourse; (5) dreams with manifest content depicting heterosexual interest or activity. Negative prognostic indicators included a history of the mother having openly preferred the patient to her husband and a history of effeminate voice and gestures during childhood.

With the exception of the flagrantly effeminate homosexual and those committed to a homosexual life style, homosexuals do not entirely renounce the possibility of change. This should be kept in mind in advising homosexuals about treatment. The experience of clinicians indicates that, even where homosexual patients have not shifted to heterosexuality, they have at least gained benefits from resolving interpersonal problems and other difficulties.

The treatment of choice is psychoanalysis or psychoanalytically oriented psychotherapy. In reconstructive treatment, emphasis is placed on delineating the irrational fears of heterosexuality, helping the patient learn how his fears developed, and, over the course of time, helping him resolve his fears.

There are therapies extant that are not indicated—in fact, they are definitely contraindicated—such as hormone treatment with androgens, which is based on the erroneous assumption of male hormonal defect. Androgen, if anything, only increases sexual

drive without affecting its direction. Drug therapy, including tranquilizers and ataractics, is not indicated for homosexuality per se but may be helpful if the homosexual patient is also suffering from a schizophrenic disorder. Electric shock therapy is strongly contraindicated.

Recently, behavioral therapy has attracted some notice. In effect, behavioral therapists apply principles of learning theory as a method of extinguishing homosexuality. The patient is negatively conditioned to his usual homoerotic stimuli. He is shown pictures with homosexual content and is simultaneously given injections of apomorphine in order to bring about an association between the homosexual stimulus and a painful experience (aversive conditioning). Although good results have been reported by some investigators, this type of treatment seems to add injury to preexisting injury. It has given little promise of lasting results and at best is ineffective.

Exhortative therapy—which relies on stimulating guilt, moral or religious—is ineffective and generally harmful, as is punitive therapy, including the legally sanctioned.

Female Homosexuality

In about 600 B.C. off the Greek mainland on the island of Lesbos in the Aegean sea, many of the young female islanders were influenced by the poetess Sappho, who encouraged them to participate in mutual sex practices. An erotic relationship between women came to be known as lesbianism.

Prevalence. There is a wider divergence in estimates of female than of male homosexual prevalence. Caprio is of the opinion that homosexuality occurs as frequently among women as among men. Havelock Ellis and Edmund Bergler, among others, share this appraisal, though it is at variance with that of Kinsey et al., who stated:

The incidences and frequencies of homosexual responses and contact and consequently the incidences of the homosexual ratings were much lower among females in our sample than they were among the males on whom we had previously reported. Among the females the accumulative incidences of homosexual responses had ultimately reached 28%. They had reached 50% in the males. The accumulative incidences of overt contact to the point of orgasm among the females had reached 13%. Among the males it had reached 37%. This means that homosexual responses had occurred in about half as many females as males and contacts which had proceeded to orgasm had occurred in about one third as many females as males. Moreover, compared with the males, there were only about one half to one third as many of the females who were, in any age period, primarily or exclusively homosexual.

If the number of female homosexuals in psychoanalytic treatment is any indicator of lesbian prevalence, there are somewhere between one third and one fourth as many females as male homosexuals. Although the clinical estimate accords with Kinsey's findings, it does not support his absolute figures, such as, "13% of all women by the age of 40 have had

homosexual experiences leading to orgasm." This difference may be attributable to sample problems; however. Statistics for the total male sample—such as the number of bachelors, the number of men who were married, separated, divorced, or widowed—were not stated, though comparable data were given for the female sample. Among the females 24 per cent between the ages of 31 and 40 had never married. The high overrepresentation of spinsters in this age group would tend to veer in the direction of increasing homosexual frequencies. Most unmarried women between 31 and 40 fail to marry because of emotional disturbances, especially sexual psychopathology. Until systematic studies are conducted on representative samples of the female population, estimates of prevalence are but guesses—some more educated than others.

Characteristics. The relationships of lesbians to each other are in the main similar to those noted among male homosexuals. In the lesbian act a heterosexual masquerade is played out; one partner takes the masculine role, the other the feminine. The participants may sometimes interchange roles, though some women are habitually "masculine," and others are habitually "feminine." In the vernacular the male emulators are called "butch." They avoid feminine dress and attitudes and to varying degrees imitate men in dress, speech, and other behavioral patterns. The feminine type is referred to as "femme." In pairings where one is butch and the other femme, the roles of husband and wife are enacted in the pathological caricatures they perceive these roles to be. The butch is aggressive, dominant, and tough. She generally initiates sexual activity. The femme is retiring, submissive, dainty—a stereotypic embodiment of soft femininity. In the context of this marital caricature, domination-submission behavior, sadomasochistic activity, and pathologic dependency are clearly evident.

These psychopathological parameters also appear in another type of lesbian pairing, where there is an acting out of a mother-daughter relationship. In this type of role play, age may be a determining factor; the woman who takes the mother role is usually older than the "daughter." The "mother" may affect the characteristics she associates with motherhood. Role play may be enacted to the point where the daughter is cradled like a child in arms during caressing sexual play.

Just as male homosexuals obsessively emphasize genital size and seek out masculine qualities in partners, lesbians seek out feminine qualities, particularly maternal characteristics as symbolized by the breasts. The lesbian's interest in breast size and shape parallels the male homosexual's interest in the size of the penis. Homosexuals of both sexes seek to repair their damaged sexual functioning by attempts at achieving a magical unity with prominent symbols of masculinity and femininity—the penis and the breast.

There is probably a greater tendency among les-

bians than among male homosexuals to establish a stable pairing. Those who live alone are prone to engage in promiscuous, superficial sexual relationships. Female partners are usually ambivalent toward each other, as occurs among male pairs. More often than not, jealousy of rivals and hostility toward them are intense. Should rejection or inconsiderate treatment be anticipated, jealousy and rage are turned against the partner. Sexual infidelity is common; hence, there exists in reality a basis for fearing rejection and abandonment. Hostility may be experienced in physical aggression, and there are cases on record of lesbian murder. In one situation a woman encouraged a successful suicidal attempt by her partner. How long lesbian partnerships endure and what percentage remain in permanent relationships are questions that must await more thorough studies for reliable answers.

Lesbian sexual practices vary among individuals and may vary in the same individuals with different partners. The repertoire of activities include manual and oral stimulation of erotogenic areas such as breast and genitals, simulated heterosexual intercourse with or without the use of an artificial penis, and passionate hugging and kissing.

Etiology. The prevailing concepts of the etiology of lesbianism follow the same general line of thought as for male homosexuality. In some circles female homosexuality is viewed as deviant but biologically normal; in others, it is deemed to be psychopathological. Most psychiatrists hold the latter view. There appears somehow to be a greater concordance that lesbianism is an acquired condition than one notes for theories about male homosexuality.

Classical psychoanalytic theory. The classical psychoanalytic position posits, first, that the earliest love object of both sexes is the mother, but, in order to attain heterosexuality, the female, unlike the male, must renounce the mother as a love object and, instead, identify with her. Females who cannot make this renunciation become fixated on the mother and may ultimately become homosexual. Such women may seek out a younger female, with whom they recapitulate the maternal role as described earlier; others take the role of daughter and seek out maternal figures. Why this occurs in some females and not in others is not clearly explicated in this schema, although such factors are considered as maternal absence, rejection or its opposite, overindulgence, and latent homosexual tendencies in the mother.

Secondly, the girl develops a castration complex consequent to her discovery that she lacks a penis. She may then become unduly preoccupied with her clitoris, which is unconsciously believed to be an analogue of the penis; she will deny her vagina. To resolve her castration anxiety successfully, the normal girl must renounce the primacy of the clitoris and accept the passive receptivity of the vagina. When a girl fails to resolve this crisis, she cannot

enter into a heterosexual relationship: because the male possesses a penis, he reaffirms her castration. She then identifies with males and holds onto the fantasy that she possesses a clitoral penis. Other women become eroticized and sought for sexual fulfillment. Rivalry with a preferred male sibling is offered as one possible explanation for clitoral fixation.

Thirdly, the vicissitudes of the Oedipus complex may determine a homosexual outcome. The decisive pathogenic factor may be a too intense attachment to the father, thus forcing a retreat from feared incestuous impulses. The oedipal phase may include sexually damaging experiential elements, such as paternal rejection or seductiveness. By adolescence, having failed to achieve the father sexually, the prehomosexual girl identifies with him and turns to a woman as a love object.

Missing in classical formulations is a coherent articulation between developmental phases and experiential elements, a linkage necessary for the illumination of differences between girls who become homosexuals and those who do not. The etiological psychodynamics as developed in classical theory are variations on one or another of three themes: (1) the inability to renounce the mother as the first love object; (2) clitoral fixation as a reaction to castration anxiety; (3) oedipal fears and disappointment.

Other theories. Bychowski added the concept of defective ego development consequent to defective parental nurturance, leading to a pathological dependency on the mother. This anaclitic relationship is then acted out through homosexuality.

Rado viewed homosexuality as a flight from the substitute for feared heterosexuality. He accounted for these fears by postulating that in the female intercourse is viewed as a penetrating attack; in some women masochistic wishes to be raped and penetrated reinforce the fantasy of intercourse as a violent act. Unable to pursue heterosexuality, she falls back on infantile dependency on her mother.

According to Thompson, homosexuality is not a clinical entity but a symptom with different meanings for different personalities. Thus, homosexuality could be an expression of fear of the opposite sex, fear of adult responsibility, a need to defy authority, an attempt to cope with hatred of or competitive attitudes toward members of one's own sex, a flight from reality into absorption in body stimulation, and a way of being destructive of one's self or others. Although Thompson did not assign specific causes for the symptom, she suggested that causal factors might include awareness that one's sex was a disappointment to parents, seen in situations where a parent treats a child as a member of the opposite sex. Thompson also pointed out that intimidating influences might be etiological, since timid individuals tend to cling to same sex persons.

Proposed theory. This writer's etiological formulation places major emphasis on the pathology of

parent-child relatedness as it affects personality development in general but more specifically as it affects and is affected by salient psychosexual maturational phases, such as the Oedipus complex in males and the Electra complex in females. The parental profiles associated with lesbianism cannot be definitive until a systematic study of female homosexuality has been done. However, from empirical and clinical evidence, the influence of parents on a daughter's homosexual adaptation is as significant as has been demonstrated for male homosexuals.

Fathers of male homosexuals have a special psychodynamic saliency because of sexual competitiveness with the son. In lesbianism it is the mother who occupies this special position. She tends at best to be ambivalent, but more often she is hostile and competitive. Rather than enhance her daughter's femininity, this type of mother defeminizes. Lesbians often describe having missed the experience of being dressed in attractive, girlish clothes during childhood or of being complimented on physical attributes; on the contrary, they recall their mother's fault finding, rejection, and control. Homosexually inductive mothers interfere with an easy, natural relationship between daughter and father and frequently discourage such closeness, even contact; they also tend to interfere with heterosexual peer relationships. Other maternal characteristics include sexual competitiveness with women, preference of sons to daughters, and rivalry with daughters for males. It is essentially for this last reason that they defeminize a daughter and, to all intents and purposes, castrate her. In another category are those mothers who have the need to create a female companion for themselves. They interfere with the daughter's heterosexuality lest she be lost to a male. Such a mother probably has homosexual problems herself, and she carries out an unconscious homosexual relationship with her daughter, who, if she does not become a lesbian, may well become a spinster.

The fathers are usually submissive to their wives and, as an expression of their submission, fail to come into an appropriate affectionate and protective relationship with the daughter. In part, paternal detachment is a submissive renunciation demanded by the mother, and, in part, it may be a defense against anxiety about sexual feelings toward a daughter. Many such fathers feel that normal sexual feelings to a daughter are unnatural. A wife may exploit this paternal anxiety by subtly, sometimes overtly, stimulating sexual guilt. Some fathers are reported as quite seductive, but they may express it in a conspiratorial way, which only highlights submission to the wife and guilt about their sexual feelings. Fathers who are strong figures in the family and who are openly affectionate and masculine with their daughters do not produce lesbians.

Emphasis is not placed here on the classical female castration complex, which assumes that a girl's dis-

covery and awareness of lack of a penis is the main pathogenic influence. Two components were differentiated by Bieber and Drellich: the phallic and the feminine. The phallic component relates to reactions to the absence of a penis. This appears to be a transitory phase, having little or no pathogenic importance unless it is made so by the influence of parental psychopathology. Mothers who treat sons preferentially, showing them a quality of affection not shown to a daughter, induce feelings of maternal deprivation. The daughter may then develop envy of males, which may be symbolized in expressions of penis envy. In the feminine component of the castration complex, the female is concerned about injury to her femininity, her feminine organs, and the functions they mediate. In lesbianism both phases of the female castration complex are integrated in personality and behavior. It is unlikely that an affectionately related mother who encourages her daughter's femininity will produce a lesbian, nor, as pointed out, will lesbianism occur when a father is assertive, affectionate, supportive, and enhancing of his daughter's femininity.

Treatment. The treatment of female homosexuals is similar to that for male homosexuals with the exception of criteria for early detection of the inversion. The criteria are not so well defined for girls as for boys. One can say, however, that tomboyishness is not necessarily an indicator of lesbian tendencies. It may indicate high spirits, a high level of energy, and perhaps an imitation of boys, who may be perceived as parentally preferred or as having a more favored position in the youth culture. Girls who show strong preferences for masculine dress or who habitually avoid more typically feminine attire and pursuits are, at the least, showing homosexual trends. The prehomosexual female, like her male counterpart, tends to be an isolate who makes defective peer relationships. During early adolescence and later, she tends to develop crushes on other girls or older, admired women. An adolescent girl who has not experienced a heterosexual crush or had heterosexual fantasies and who avoids dating and shuns contact with boys is having sexual difficulties, whether homosexual or not. Psychiatric consultation is indicated for such a girl. If consultation confirms homosexual tendencies, the patient should be treated, as should her parents, if this is feasible. Psychotherapy in early adolescence favors the establishment of a heterosexual adaptation.

26.4 SEXUAL DEVIATIONS. III: FETISHISM, TRANSVESTITISM, MASOCHISM, SADISM, EXHIBITIONISM, VOYEURISM, INCEST, PEDOPHILIA, AND BESTIALITY

SANDOR LORAND, M.D.

HENRY I. SCHNEER, M.D.

Introduction

Psychoanalytic investigations of sexual deviation were initiated by Freud's discovery, in the course of his study of infantile sexuality, that the sexual aims of the deviant are identical with those of the child. More specifically, in sexual deviation, adult sexuality is supplanted by infantile sexuality. In fact, however, this represents an oversimplified formulation of the current psychoanalytic concept of sexual deviation and requires further elaboration.

At the outset, it should be pointed out that sexual deviations have been practiced throughout history, among all races; and at certain times and in certain cultures they have been generally accepted or even highly esteemed. Thus, Freud described sexual deviations as "universally human." Deviant tendencies, and even occasional deviant acts, or at least fantasies, occur in the life of every individual—normal and neurotic alike. Fenichel's comment in this connection is particularly appropriate: "Since the aims of perverse sexuality are identical with those of infantile sexuality, the possibility for every human being to become perverse under certain circumstances is rooted in the fact that he was once a child." In other words, perverse or deviant acts are exaggerated distortions of acts which also occur as part of the sexual behavior of normal individuals. The crucial difference lies in the fact that the deviant act does not represent the sole source of sexual gratification for the normal individual; consequently, it will take a less definite form.

To illustrate, in a sense the polymorphous activity which is characteristic of sexual foreplay prior to intercourse represents a regression to infantile sexuality. However, in our culture, such foreplay is appropriately regarded as normal sexual behavior. It becomes pathological only when the initial aspects of coitus (i.e., forepleasure) are more satisfactory than genital union with a "willing partner of the opposite sex and of similar sexual maturity."

While foreplay (as the primary source of sexual pleasure) is a useful example of sexual deviation in this context, it may be somewhat misleading. Actually, pathological states which represent nothing more than a regression to infantile sexuality are not typical deviations. Like the normal adult, the typical

deviant can achieve genital orgasm once the obstacles which block sexual gratification are removed by the deviant acts. The point is that deviant sexuality is not simply disorganized, in a manner reminiscent of the "polymorphous perverse" sexuality of children and of infantile personalities. Rather, it is organized under the guidance of one component instinct of infantile sexuality; the satisfaction of this instinct makes genital orgasm possible again.

Like the neurotic, the deviant has specific pathogenic repressions: he has unconscious oedipal conflicts and unconscious castration anxiety. Similarly, disturbances in genital primacy in neurosis and sexual deviations alike may be attributed to the same factors—anxiety and guilt feelings which are associated with the Oedipus complex. But anxiety over loss of love or sexual excitement is less important in sexual deviation. Rather, classical psychoanalytic theory postulates that it is always castration anxiety (and derivative guilt feelings) which prevent the deviant from achieving sexual pleasure. The sexual deviation serves, then, as a denial of the possibility of castration. When this denial is successful, sexual pleasure and orgasm become possible.

Diagnostic classification. Various criteria exist for the classification of sexual behavior, in general, and deviant sexuality, in particular.

In the American Psychiatric Association's *Diagnostic and Statistical Manual*, sexual deviation is listed as a form of sociopathic personality disturbance. Sexual deviation is the official nosological designation and is synonymous with and preferable to the term "perversion." The *Manual* further states that this major clinical entity encompasses those individuals who are ill "primarily in terms of society and of conformity with the prevailing cultural milieu, and not only in terms of personal discomfort and relations with other individuals." Within this larger category, the diagnosis of "Sexual deviation...is reserved for deviant sexuality which is not symptomatic of more extensive syndromes, such as schizophrenic and obsessional reactions."

Within a broader framework, Scott has classified normal, as well as abnormal, sexuality in terms of specific patterns of behavior: (1) Sexual gratification requires the cooperation of a willing partner (e.g., homosexual or heterosexual activity). (2) The cooperation of a willing partner and genital union as a means of achieving pleasure are discounted (e.g., exhibitionism and voyeurism). (3) Sexual gratification does not require the cooperation of a human partner. Instead, things (fetishism), or animals (bestiality) are substituted for the object. (4) The individual is unable to achieve full genital satisfaction (e.g., frigidity or impotence).

The psychoanalytic classification of sexual deviation, which has important implications for therapy, ascribes deviation to either regression or arrested development.

When deviation is due to regression, the patient has demonstrated a capacity for adequate heterosexual relationships in the past, together with an awareness of (and a desire to conform to) the mores of his cultural milieu. The factor, or factors, responsible for deviant sexuality are readily apparent or easily uncovered in such cases. Most frequently, the deviant behavior is precipitated by disappointment in love (i.e., sexual disappointment), and a consequent loss of self-esteem, or by conditions which serve to revive intense childhood fears and/or dependency needs. Finally, real obstacles to sexual satisfaction, or sexual privation, may bring deviant tendencies to the surface. Whatever the specific precipitating factor or factors, persons who react to sexual frustrations with a regression to infantile sexuality are said to deviate. And such patients are infantile in nonsexual respects as well.

When sexual deviation is due to arrested development, the patient has consistently proven incapable of an adequate heterosexual relationship, although no real external obstacle to the development of such a relationship existed. And, as might be expected, the factor or factors responsible for deviant sexuality in such cases cannot be identified accurately without a thorough knowledge of the patient's developmental history.

Historical evolution of psychiatric concepts of sexual deviation. First indications of the recognition of sexual deviation as a psychopathological disorder may be found in Westphal's description of homosexuality as "contrary sexual feeling" in 1870, and Lasègue's reference to exhibitionism in 1877. Subsequently, Krafft-Ebing maintained that perversions were hereditary; however, he later conceded that "accidental causes" might play a role in such disorders. Kraepelin described sexual deviations as "inversions," and a form of degeneracy. In general, until publication of Freud's *Three Essays on the Theory of Sexuality*, in 1905, perversion was considered to represent a genic or constitutional anomaly, which, in effect, precluded serious investigation of this problem. Thus, Freud's delineation of specific stages of psychosexual development had important implications for the understanding of sexual deviation—and of all mental and behavioral phenomena. Within this ontogenetic frame of reference, sexual deviation could be understood as representing either an arrest in psychosexual development or a regression to a previous, infantile level of functioning.

Current Psychiatric Concepts of Sexual Deviation

Etiology

Constitutional determinants. Proponents of genic-constitutional theories of perversion point to the presence of biological anomalies in some sexual deviates as evidence in support of their proposition. In

fact, however, these individuals represent only a small proportion of this total patient population. Furthermore, the fact that the presence of such anomalies does not necessarily indicate sexual deviation is an even more convincing argument against this hypothesis. For instance, in cases of hermaphroditism, where the same individual possesses both male and female genitalia, homosexuality is infrequent. For the most part, male hermaphrodites (by the presence of testes) are emotionally inclined to relate to the female, i.e., heterosexually. Nor is there any evidence, on the basis of available endocrinological data, that larger or insufficient quantities of hormones can influence the individual's direction of drive or his choice of sexual object. Androgens control the strength and vigor of sexual expression, but they cannot control the direction of the drive. In summary, there is little evidence to support the hypothesis that hereditary and constitutional factors are an important determinant of sexual deviation.

Classical psychoanalysis ascribes to this viewpoint, based on other considerations. The fact that fixation determines the choice of the component of infantile sexuality which is overattached in the sexual deviation means that the assumption that such deviations are constitutionally determined does have some validity. However, once again, the endocrinological evidence is not convincing. Furthermore, the fact that normal persons are capable of deviant sexuality under certain conditions is conclusive proof of the limited importance of constitutional factors in the etiology of sexual deviation.

Finally, deviant sexual behavior due to brain lesions has been reported in the literature. However, in such cases, one must assume the prior existence of tendencies toward deviant sexuality and speculate that these tendencies may have been "released" by the organic trauma. On the other hand, brain lesions in early childhood produce distortions in perception and experience; the child's learning capacity is affected as a result, which, in turn, may lead to subsequent modifications in his sexual behavior.

Sociocultural determinants. Social anthropologists and ethnologists have called attention to the fact that different societies demonstrate marked differences in sexual orientation. These authors have also described the obvious implications of these diverse social attitudes for adult sexual behavior, often with particular emphasis on variations in cultural attitudes toward those sexual activities which are considered abnormal in our society. Nevertheless, no matter how permissive a particular society may be with regard to sexual behavior, certain universal attitudes toward sexuality remain unchanged. Malinowski has commented, in this connection, that . . . "the sexual impulse is never entirely free, neither can it ever be completely enslaved by social imperatives."

However, disregard of social imperatives may result in harm to the community as an entity and there-

fore constitutes a public offense. Even within the scope of one's own permissible sexual behavior, because of fear attributable to sex taboo infractions, there is a likelihood of somatic illness. The powerful sanction of public disgrace can bring on hypochondriasis or psychosomatic illness.

However, the significance of environmental factors in the etiology of perversion should not be minimized. On the basis of detailed ethnological observations, Ford and Beach suggested that "... human sexual patterns are not completely organized on a strictly inherited level. Instead, it is highly possible that practice is essential to complete arousal and particularly to satisfactory expression of sexual excitement." In other words, there is a strong possibility that an environment which is too interfering or restrictive with regard to sexual "practice" may be conducive to the development of sexual deviation. But, contrary to popular belief, the extent to which abnormal sexual behavior is tolerated is not the measure of a "healthy" environment. Rather, it is the extent to which the youth of a particular society are given an opportunity to develop in all areas, to mature for engagement in genital union with members of the opposite sex.

For example, among the Keraki of New Guinea, the young initiate must submit to pederasty (i.e., anal intercourse) with the elders of the tribe, as a means of acquiring the older men's strength and status. But these sexual relationships are charged with aggression; the genitals are not used to express harmonious, mutual love. In other words, just as culturally determined high evaluation of epileptic states does not signify the absence of underlying brain pathology, the fact that certain sexual practices which are considered deviant by our cultural standards are acceptable in other cultures cannot alter the pathological significance of such behavior. The fact remains that, whatever the cultural attitude toward such practices, sexuality which does not find expression in mature, genital union must be considered deviant.

Psychological determinants. According to classical psychoanalytic theory, the pathogenesis of sexual deviation in the individual patient can only be understood after careful study of his psychosexual development. Freud postulated that the sexual instinct was endowed with energy, which he called "libido." This energy enables the performance of physiological functions, which, in turn, permit discharge (and gratification) of the instinct. At different stages of psychosexual development, the sexual instinct will vary in source, aim, and object. During infancy and early childhood, sexual activity is "polymorphous perverse." Sexual excitation flows from diverse sources, and excitation and gratification are experienced in conjunction with such activities as sucking, defecation, and stroking. Only at a later stage in psychosexual development (usually during

puberty), do the genitals become an erogenous zone which offers possibilities for sexual pleasure infinitely greater in comparison with earlier oral and anal zone pleasures. When the penis (or vagina) draws to it the erogenicity of the other zones, the child has reached the stage of genital primacy. In the normal course of development, oral and anal urges and activities now serve a preliminary function (as foreplay) rather than a satiation function.

Concurrent with the progression of the stages of psychosexual development, i.e., oral, anal, urethral, and phallic or genital, Freud described specific phases in the development of object relationships during childhood. Initially, and for some time thereafter, the infant's sexual activities are autoerotic: the first object is his own body and its functions. In a subsequent stage of his development, the child turns to another for "object love." However, the sexual object need not be a member of the opposite sex. Furthermore, in addition to homosexual and heterosexual impulses, masochistic and sadistic impulses may find expression—further evidence of the polymorphous perverse activity which characterizes this early phase of development.

Within the framework of classical psychoanalytic theory, the origins and structure of sexual deviation may be presented schematically as follows.

Raw material. Essentially, infantile forms of libidinal and aggressive drive expressions are the raw materials of sexual deviation. Consequently, in the psychoanalytic treatment of sexual deviation, the infantile drives at each consecutive phase of development must be "worked through." As stated earlier, the deviant has regressed to that part of his infantile sexuality at which he is fixated. However, deviant sexual excitement is first experienced in association with "accidental" events of childhood, and it has been suggested that the individual's sexual reactions remained "bound" to these events. In fact, psychoanalytic investigations have shown that these childhood events may not be fixating experiences in themselves. The same event may be fixating for one individual and not for another, according to one's capacity to cope with stimulation. Furthermore, the "fixating experiences" may serve as a screen to disguise memories of the real causes for the fixation.

Phase-specific vicissitudes. Deficient mothering in the earliest (pre-oedipal) months of life is assumed to interfere with the development of a healthy ego. In subsequent childhood phases of development, the child with a disadvantaged ego is burdened by castration anxiety, which further impedes his successful resolution of the Oedipus complex. In structuring the form of the sexual deviation, the epigenetic process of coping with the castration anxiety which is an inevitable concomitant of the oedipal phase of development is of crucial significance.

Decisive etiological factor. Sexual deviation is the acted out, defensive denial of castration anxiety.

Fenichel has pointed out that when genital enjoyment is blocked by fear of castration, the deviant will try to regress to that component of his infantile sexuality which once gave him a feeling of security, or at least of reassurance, and "whose gratification was experienced with special intensity because of this reassurance." At the same time, however, other components of infantile sexuality are repressed, and the hypertrophy of this one component serves to strengthen the repression. In other words, the fact that certain associated impulses which are usually forbidden are permitted to remain in consciousness reinforces the repression of the Oedipus and castration complexes.

Finally, Fenichel has also pointed out that "... the differences in the male and female castration complex directly correspond to the differences between male and female perversions."

Nature of the deviant impulse. The deviant act may or may not elicit guilt feelings. Nevertheless, at the moment his excitement is most intense, the deviant's impulse is ego-syntonic. That is, it is something he wants to do for pleasure. Thus, deviant impulses have an instinctual character and, as Fenichel has pointed out, are "felt in the same way that normal instinctual impulses are felt by normal persons."

Self-centeredness of personality makeup. The deviate is preserved from close ties to another, remains narcissistic in object relationship because of a split in ego. One side of the ego is allied with the impulse to be gratified, and the other side is allied with that aspect of the object associated with early childhood. So true object, mature love does not occur.

Differential diagnosis. Sexual deviation may be encountered as a specific presenting problem in clinical practice. However, early in the course of treatment its implications as a symptom of a broader diagnostic category (i.e., sociopathic personality disturbance) become evident. In other words, the "end" behavior (i.e., the deviant act) and its manifest effects must be distinguished from factors which have given rise to such behavior.

The psychodynamics of the etiology of deviation as a psychopathic disturbance were delineated above. In addition, deviant tendencies may be released by organic illness, mental deficiency, or schizophrenia.

For example, in encephalopathy, impaired ego functioning may weaken impulse control and give rise to sexually deviant behavior. Again, deviation may serve a defensive or restitutional function in states of increased organismic excitability due to cerebral pathophysiology. It may be speculated that in such cases the sexual deviation absorbs or binds the anxiety lest it "explode" or manifest itself otherwise. However, once the cerebral pathophysiology is relieved, the deviation is no longer needed.

Anxiety is also prominent among mental defectives. And, among this patient population, suggestibility, particularly under the emotional stress of increased

demands on their facultative capacities, frequently gives rise to deviant sexuality.

Finally, the schizophrenic's impaired capacity for reality testing may also find expression in deviant activities. Deviant acts and fantasies are a prominent feature of the paranoid psychoses as well.

When sexual deviation accompanies a major affective disorder, it may be primary or reactive. For example, hypomanics in whom superego criticism has been suspended frequently display deviant behavior, which lasts as long as the manic phase. On the other hand, depression and suicidal behavior may be reactive to the shame of threatened exposure of the deviation.

Sexual deviation has a compulsive quality: in a sense, the deviate behavior is repeated against the conscious wishes of the patient. However, deviation is not a compulsion neurosis. By enabling discharge of a part of the cathexis of impulses which had been warded off originally, the deviate symptom, like the neurotic symptom, facilitates the warding off of other impulses; i.e., it strengthens repression. But neuroses differ from deviations in two crucial respects. First, the symptom is "desexualized" in the neurosis; in the deviations it is a component of infantile sexuality. Second, in the neurosis, discharge of the symptom is painful; in deviation, it brings genital orgasm. The compulsive symptom represents an act of undoing whose purpose is the expiation of guilt feelings. Accordingly, the superego forbids enjoyment of the activity. In contrast, in deviation, at the moment of excitation, the deviate impulse is experienced as ego-syntonic and has the quality of an instinct. The superego is defiantly seduced into permitting the costly pleasure derived from discharge of the deviate impulse. Thus, discharge becomes possible only through distortions, and Freud described deviates accordingly as "poor devils who have to pay a high price for their limited pleasure."

One final factor must be considered in the differential diagnosis of deviation. As noted earlier in this section, deviate acts occur in the life of every individual. It was also pointed out, in this connection, that deviate tendencies may be released under certain abnormal conditions, such as the deprivation of normal sexual outlets for an extended period of time and organic disease. In such instances, the deviate behavior usually disappears once the abnormal condition to which it is attributed has been corrected.

Similarly, the psychodynamics of certain stages of development are particularly conducive to the discharge of nonpathological, transient deviate sexuality. For example, during the early phases of adolescence, strong tendencies toward impulsiveness, to act out bisexual conflicts, and increased self-awareness and narcissism may give rise to sexual deviation which, however, is usually transient. Commitment to a sexual deviation is more likely to occur in late adolescence.

Management and prognosis. Various procedures

have been employed in the treatment of sexual deviation. Although no specific method is currently considered to represent an ideal solution to this problem, psychoanalysis is advocated by many workers as the most effective therapeutic approach to sexual deviation. Manipulation of the environment and group therapy have also proven helpful in some cases, although such procedures would not be expected to investigate the genesis of the problem in depth; nor can they be expected to provide lasting benefits in cases of deep-seated sexual deviation.

As might be expected, prognosis, with treatment, is most favorable in those cases where the relationship between the deviate behavior and precipitating environmental factors can be clearly established, and among individuals in early and middle adolescence. The prognosis for other segments of this patient population is generally discouraging. The symptoms of sexual deviation are pleasurable. Therefore, unless the patient is particularly anxious or depressed about his behavior, there is little incentive for him to seek treatment. Even if he is not "at peace" with his sexual deviation, he may seek treatment for his "neurotic" reactions, with the understanding that he will be permitted to keep the sexual deviation.

The sexual deviations (with the exception of male and female homosexuality) which are encountered most frequently in clinical practice are described below, with specific reference to the nature of the deviate activity, its frequency, the psychoanalytic concept of its etiology, clinical description, management of the disorder, and prognosis.

Fetishism

Definition. The fetishist achieves sexual excitement and gratification by substituting some inanimate material object (e.g., shoes, corsets) or some part of the body (e.g., a foot or a lock of hair) for a human love object. With regard to the specific fetish chosen, Kinsey felt that there might be a connection between fetishism and sadomasochistic behavior, as evidenced by the aggressive quality of some of the objects which typically arouse sexual excitation (e.g., whips, tight corsets).

Apart from such considerations, various authors have described the fetish as representative of the female, as well as the male genitalia. However, psychoanalytic clinical investigation has shown that, almost without exception, the fetish is symbolic of the penis.

Epidemiology. Fetishism is a defense against castration anxiety (as are all sexual deviations). Since the fetish is usually a penis symbol, it is logical to assume that fetishism would be demonstrated almost exclusively by males. Obviously, one would not expect a penis symbol to reassure a female of her possession of a penis. This hypothesis has been confirmed by the findings of Kinsey et al. who reported "only two or three cases" of female fetishism among the population studied.

Etiology. As early as 1927, Freud explained fetishistic deviations in males as the result of overpowering castration anxiety which originates in early childhood. For the young boy, the absence of a penis in females is a reminder that this could happen to him, and it revives his fear of castration. Consequently, he refuses to accept the fact that women have different genitalia from men. Confronted with reality at a later stage in his development, he turns away from the living object to replace it with the fetish, which stands for a female penis. Sexual excitation and gratification are possible only when he can convince himself of the existence of a female penis, for only this belief can keep his castration anxiety in abeyance.

Epigenetically, the development of fetishism presupposes that the patient was exposed to the sight of the female genitalia in early childhood, and that the anxiety provoked by this experience was so intense that there was a corresponding need to deny the perception. Thus, the ego is split: on the one hand, there is an awareness of the female genitalia; on the other hand, this knowledge is denied. This split in the ego serves another function as well: belief in the existence of a female penis wards off incestuous impulses.

Traumatic experiences in early life are believed to accentuate and contribute to the fear of genital mutilation, and the subsequent development of fetishism.

One such fetishist patient had had an operation on his penis for phimosis at the age of 3. Lorand has described another patient who was operated on for pes varus as an infant and had his foot in a cast for months.

Clinical description. The fetishist cannot become completely involved in a heterosexual relationship. Yet, he is unhappy with his sexual way of life; he is frequently depressed and moody and, at times, may drink excessively. Nevertheless, he is usually well liked by both men and women and has many friends. In fact, the fetishist's reserved attitude makes him attractive and "interesting." The fetishist is interested in establishing social contact with women, and his conversation may be very seductive, but he rarely proceeds beyond this point; i.e., genital contact is avoided.

The fetishist may also present a passive, shy facade, which conceals a violent temper, obsessional trends, and feelings of general distrust. Typically, he shows a high degree of sensitivity. The tendency toward denial, which is a prominent feature of fetishism, may lend a prepsychotic quality to his behavior.

For the female fetishist, kleptomania may be a source of sexual excitement. Frequently, such patients compulsively steal and accumulate objects which have no material value, but which have unconscious sexual significance.

Prognosis. The success of treatment will depend

on the strength of the fetishist's desire to change, that is, for a normal heterosexual relationship. Fetishists who were well motivated along these lines have been cured of their symptoms.

Management. Any therapeutic technique which serves to reassure the patient is helpful. However, psychoanalysis is the most effective treatment method because it exposes the oedipal and pre-oedipal factors which gave rise to the castration anxiety the patient tries to overcome through fetishism. Within this frame of reference, the techniques used in the psychoanalytic treatment of fetishism will not differ significantly from those employed in the treatment of any other severe neurosis, except that greater tact and flexibility will be required of the analyst. In general, treatment will focus on strengthening the patient's ego, so that he is better able to control the discharge of impulses, and on uncovering and "working through" repressions and early fixations, so that the patient will no longer find it necessary to resort to infantile modes of sexual expression.

Transvestitism

Definition. The transvestite achieves sexual excitation and gratification from wearing the clothes and enacting the role of the opposite sex.

Epidemiology. In Kinsey's sample transvestitism was most prevalent among men: "There may be a hundred anatomic males who wish to be identified as females, for every two, or three, or half dozen anatomic females who wish to be identified as males." (However, other authors have pointed out that in about a dozen primitive societies, females customarily dressed as males and assumed the role of the male in their social organization.) Kinsey further stated that "The data shows that only a portion of transvestites have homosexual histories." However, the clinical evidence indicates that, not infrequently, transvestitism is part of a triad, along with fetishism and homosexuality.

Etiology. Although there is some disagreement as to the etiology of transvestitism, it is generally accepted that constitutional predisposition is a necessary (but not sufficient) precipitating factor. Psychoanalytic theory postulates that, in essence, transvestitism has its origins in the oedipal and pre-oedipal phases of development, that it represents a psychic regression to infantile sexuality. More specifically, according to psychoanalytic theory, the aim of transvestitism is, once again, to deny the threat of castration. The transvestite, like the fetishist, overcomes his castration anxiety by clinging to the belief that the female has a penis. However, he carries this denial one step further by identifying with the phallic woman. Thus, the difference between homosexuality and transvestitism lies in the fact that, whereas the homosexual identifies with the mother by imitating her object choice, the transvestite identifies with the mother by imitating "her being a woman."

Fenichel has pointed out that the transvestite act has two unconscious meanings. The first of these is object-erotic and fetishistic: "The person cohabits not with a woman, but with her clothes; the clothes representing, symbolically, her penis." (And Kinsey has speculated, in this connection, that the female clothing may also encourage a rape fantasy.) Secondly, the transvestite act has an unconscious narcissistic meaning: "The transvestite himself represents the phallic woman under whose clothes a penis is hidden. Transvestites who are exhibitionistic about displaying their female attire show their symbolic penis in the same manner and for the same reason as the true exhibitionist actually shows his penis. Behavior of this kind presupposes a rather narcissistic orientation."

The female transvestite cannot, of course, convey the illusion that she possesses a penis, simply by putting on a man's clothing. She "plays at being a man." The difference between the male and female transvestite, then, is that although the male "plays at being a woman," he can prove to himself (through masturbation) that he has not lost his penis in the game. The female cannot reassure herself in the same way; she can only pretend. In other words, the female transvestite displaces her envy of the penis onto an envy of the masculine appearance. Fenichel further suggested that male transvestitism has "a more serious character; female transvestitism has a pretending character."

Other authors have emphasized the importance of the bisexual disposition in the etiology of this sexual deviation. More specifically, a preeminent factor in the psychopathology of the transvestite is the confusion which has surrounded his sense of sexual identity from the earliest phases of personality development. For example, it is quite common to find that, as a child, the male transvestite liked to dress up in his mother's or sister's clothes, that the female transvestite dressed up in her father's or brother's clothing. While this may be a transient phenomenon in normal childhood, in the transvestite the impulse to emulate the opposite sex remains unmodified.

Disturbances in object relationships, while not unique to transvestitism, are also typical of the early history of these patients. Thus, we find that, almost without exception, the male transvestite was the center of his mother's attention during the crucial phases of his development, and the mother was often quite seductive. Sleeping with mother or sister, observing mother in the bathroom, watching her body, taking baths with her, are all part of the traumatic sexual overstimulation to which the transvestite was exposed in early childhood.

In transvestites we also see an especially strong fear of being rejected and abandoned. Any frustration by mother is experienced as an abandonment. At the same time, there is an insatiable craving for love and affection. Wearing female undergarments enables the male transvestite to achieve the bodily

closeness to mother which he yearns for. And, it serves another function as well: by dressing in women's clothing, he is able to repress his incestuous impulses.

Clinical description. Clinically, the transvestite resembles a borderline schizoid personality. Because, above all, he is afraid of being found out, the transvestite is moody and depressed, secretive, taciturn, and distrustful. Many of these patients have heterosexual relationships. But prior to a heterosexual engagement, the male transvestite frequently dresses up in private in female underwear, an elaborate robe, and applies heavy makeup. Once he has adopted the female identity, he is able to reach orgasm through masturbation. He then changes into his regular attire and is ready to resume his "normal" life.

Prognosis. As mentioned earlier, transvestite patients usually display fetishistic and homosexual symptoms as well, which, in itself, is discouraging in terms of their general prognosis. Treatment is further complicated by the fact that patients in this category are extremely reluctant to alter their deviate behavior.

Management. Theoretically, transvestitism belongs in the category of impulse neuroses and can be treated effectively as such. In fact, however, transvestites are not suitable candidates for the deep analytic therapy which would be required to get at the root causes. For one reason, as mentioned above, transvestites are rarely motivated to seek treatment for their deviation. Secondly, it is particularly difficult, because of their nature, to expose and work through the deep-seated ego disturbances which underly this disorder.

On the other hand, while they are not eager to change their deviate behavior, the transvestite may feel the need for therapy because of the anxiety and depression which are typical in such cases, and psychopharmacological agents may help to control these reactions. Again, when the transvestite has come into conflict with his environment, relief from symptom exaggeration can sometimes be achieved. For instance, the transvestite may learn to control his penchant for exhibitionistic "dressing" and to confine his deviation to the privacy of his home.

Masochism and Sadism

Definition. Krafft-Ebing coined the term "sadism" after the Marquis Alphonse François de Sade, French revolutionary and 18th century novelist. The term "masochism" referred to the sexual practices of Leopold von Sacher-Masoch, the 19th century Austrian novelist. Schrenk von Notzing called both sexual deviations "alogagnia," meaning pleasure in pain; sadism was an active alogagnia, and masochism a passive alogagnia.

In current psychiatric practice, sadism is defined as the attainment of sexual excitation and gratification by inflicting pain upon the sexual object; the masochist achieves sexual excitation and gratification by enduring pain inflicted upon the self as an object.

Epidemiology. Many anthropological studies of other societies have emphasized the violent character of their sexual act. Thus, for example, Høleberg observed that the Sirinos bite and scratch each other during the sex act: "Charabi women spit in their lover's face during coitus, and an Alpinay woman bit a piece off her partner's eyebrows." Malinowski described similar practices among the Trobriand Islanders. Other authors have also pointed out that male mammals of many species attack the female during coitus. Zuckerman has described the male baboon's aggressive attitude, and Hamilton observed the aggressive behavior of the macaque monkey during intercourse.

With regard to our own society, Kinsey found that among the sample he studied, "Fewer females and more of the males erotically responded to sado-masochistic stories. Three percent of females had a definite and/or frequent response as compared with ten percent of males who did."

Etiology. Detailed descriptions of the psychodynamics of sadism and masochism are rare in the psychiatric literature. However, psychoanalytic investigations have shown that, once again, the definition of sexual deviation as a means of warding off castration anxiety is applicable to these phenomena as well. More specifically, the sadist is able to rid himself of the fear of castration and achieve sexual pleasure only when he is able to do to others what he is afraid may be done to him. The masochist's ability to achieve orgasm is similarly disturbed by anxiety and guilt feelings, which can only be alleviated by his own suffering.

Freud demonstrated that sadism and masochism are complementary phenomena. He concluded, on the basis of clinical evidence, that masochism is not the manifestation of a primary instinct but originates from sadism. Because the sadistic impulses toward the object are unacceptable, they are turned around and directed against the self (the ego) instead.

As mentioned above, the masochist is denied sexual gratification because of castration anxiety and concomitant guilt feelings. Fantasies of being punished as a means of alleviating these guilt feelings are very common among this patient population. For example, among women, fantasies of being humiliated, enslaved, and of being whipped, driven, and denuded by the "slave trader" are frequently encountered in clinical practice. In other words, as Fenichel has pointed out, the masochist "shifts the emphasis to the tensions of forepleasure and builds up elaborate fantasy structures, a procedure that often makes masturbation more gratifying than the actual realization of deviate activities which could not fulfill all the anticipated details... the complicated fantasy system tries to overcome the fear that blocks the capacity for end pleasure."

Childhood feelings of abandonment and rejection by the parent create feelings of rebellion, as well as

hate and resentment. Defending himself against these as well as against his castration anxiety, the masochist symbolically castrates himself, thereby saving himself from real castration. The sadist, on the other hand, symbolically "identifies with the aggressor," and "castrates" his victim to prove to himself that he is the castrator and not the castrated.

Clinical description. The clinical features of masochism have been described in greater detail in the literature than have those of sadism. Typically, the masochist feels helpless, worthless, depressed, and guilty. Clinical studies have shown, too, that masochists often show a tendency to addiction.

Variations in masochistic behavior have also been observed in this patient population. For example, the "moral" masochist seeks humiliation and failure, rather than physical pain. Moreover, the connection between his masochistic activities and fantasies and sexuality is not always readily apparent. Clinical investigation will show, however, that for the moral masochist enjoyment of humiliation symbolizes being the father's sexual object, who is beaten by the father initially, and later beaten by destiny.

Clinical observation of this patient population also serves to confirm Freud's hypothesis that both sadistic and masochistic strivings regularly appear in the same person. A male alcoholic patient who was extremely sadistic toward women in his social relationships became extremely masochistic and submissive in his sexual practices. He could perform intercourse only after his sexual partner had urinated in his mouth.

Another patient constantly read the type of magazines which deal with torture fantasies, and flagellation. At times, he fantasied that he was torturing a female victim; at other times, he was tortured by his sexual partner. During such fantasies he used to masturbate. Although he was able to engage in sexual intercourse, he found his masturbatory torture fantasies more gratifying than genital union.

Prognosis. When the sadomasochist seeks treatment on his own initiative, his prognosis is good.

Management. The fact that the masochistic patient demonstrates a need for self-punishment which is due to excessive unconscious guilt is readily apparent. Treatment must devote itself to the reduction of this unconscious guilt. Quite apart from the sexual implications of his sadomasochism, the patient must be made aware of the range and strength of his aggressive impulses. For only then can he recognize the relationship between the repressed aggressive impulses, which have their origins in earliest childhood, and his later sadistic drives with their erotic implications.

Exhibitionism

Definition. Exhibitionism, which is one of the more common sexual deviations, was first described by the French neurologist, Lesègue, in 1877. By defini-

tion, it is an impulsive action which consists of the exposure of the genitalia as a means of achieving sexual excitation and gratification.

Epidemiology. Exposure of, and the desire to look at the genitals is normal in young children, and these activities, often occur in conjunction with sexual exploratory games. Thus, Kinsey reported that "It is not impossible that nearly all boys have some pre-adolescent genital play with other boys or with girls. . . . For about 20 per cent of the boys who do engage in such play heterosexually, the exhibitionism is the limit of the activity."

In later life, genital exhibitionism, as a sexual deviation, does not exist in women. And none of the cases in female samples studied by Kinsey derived erotic satisfaction from public display of their genitalia. On the other hand, the exposure of nongenital parts of the body for the purpose of forepleasure is more common among females than males.

Etiology. According to psychoanalytic theory, the underlying psychodynamics of exhibitionism may be summarized as follows. Exhibitionism serves as a reassurance against castration anxiety in several ways. First, by exhibiting his penis, the exhibitionist says to his audience, "Reassure me that I have a penis by reacting to the sight of it." Second, particularly when the exhibitionist performs before little girls, he is saying, unconsciously: "Reassure me that you are afraid of my penis, that is, that you fear me." Finally, exhibitionism may be a magical gesture: "I show you what I wish you could show me." The mechanism here is similar to that involved in transvestitism: the deviate seeks assurance that the female has a penis in order to alleviate his castration anxiety.

Clinical description. Although exhibiting the penis is aimed at excitation, it does not generally end in orgasmic gratification. The exhibitionist gets final relief from his sexual excitement and tension by masturbation, usually manual, although his fantasies concerning the exhibitionistic experience may lead to spontaneous orgasm by seminal emission.

The exhibitionist seeks exposure, and he must roam the streets. At home, he is insecure and lonely. There is an obvious lack of self-control with regard to aggressive drives, which, in turn, implies a maladjustment in his relationship with early environmental authority figures. Sadistic and masochistic drives are geared for discharge of rebellion. Exhibitionists are repetitious transgressors of moral and social taboos. Consequently, they keep reinforcing a strong sense of guilt and need for punishment. Frequently, they risk being apprehended by repeatedly returning to the scene of their "crime," until they succeed in getting caught.

Prognosis. Because the exhibitionist rarely seeks therapeutic help voluntarily but is usually referred by the court for therapy, his prognosis is generally unfavorable.

Management. Psychoanalysis is an effective treatment method, especially for young individuals, provided the exhibitionist's desire to change is strong enough.

Voyeurism

Definition. Voyeurism was first described by French authors as a means of achieving sexual excitation and gratification by watching nude women or a man and woman engaged in intercourse.

Epidemiology. Kinsey reported that 30 per cent of the men and 19 per cent of the women in his sample preferred coitus with at least some light. Hamilton found that 20 per cent of the females and 65 per cent of the males he studied had done actual peeping. However, the percentages for the population as a whole are probably higher. For instance, strong interest and pleasure in examining pornographic pictures and films, which are quite acceptable in many social circles today, would actually be considered a sexual deviation.

Etiology. Sexual curiosity and libidinal excitement as a result of the sight of the love object are part of normal sexual development. In early childhood this sexual curiosity focuses on the parents; the adult voyeur is given to spying on strangers. Nevertheless, the voyeur is fixated on an expression of his early curiosity, which aroused his castration anxiety, such as witnessing the primal scene or the sight of the adult genitals.

As always, behind the castration anxiety there is a great deal of aggression. Deviant voyeurism aims at avoidance of the "complications" of the love relationship—the dependence and the frustrations—and, at the same time, it expresses the voyeur's resentment and hatred of the object. The sexual deviation is also an act of defiance and rebellion against the superego.

In fact, no sight can actually provide the voyeur with the reassurance against castration anxiety which he is striving for. As a result, either he develops an insatiable urge to see more and more, again and again; or his interest in watching genital activity is displaced onto forepleasure activities and even pre-genital activities.

Clinical description. In case histories, one finds that, typically, the voyeur suffered severe frustrations and rejection during the pre-oedipal and oedipal stages of his development. As an adult, he feels that his deviation is an attempt to recreate exciting, pleasurable childhood scenes with his mother. Watching forbidden exciting scenes reminds him of past pleasures, i.e., of watching his parents in their bedroom or toilet.

Prognosis. Voyeurs can be helped when they come for therapy on their own.

Management. The voyeur is frequently motivated to seek treatment because of difficulties in heterosexual relationships. At other times, his fear of being discovered and punished by the law is a focal point for

initiating treatment. In any event, voyeurs respond to psychotherapy. However, their unconscious need for punishment usually requires a psychoanalytic approach.

Incest

Definition. The word "incest," derived from the Latin, *incestum*, meaning low, poor, not chaste, commonly refers to coitus between members of the same family—father-daughter, brother-sister, mother-son—although anthropologists have extended this definition to apply to genital union between members of the same tribe or clan as well. Incest between parent and child is generally considered a form of intrafamilial pedophilia, described below. Incest may also have homosexual implications when, for example, it occurs between father and son.

Epidemiology. Freud's description of the incest taboo as "one of the most powerful prohibitions of mankind" has been confirmed by subsequent anthropological and sociological studies, as have his hypotheses concerning the origins of this taboo.

Thus, for example, the majority of the societies surveyed by Ford and Beach—72 per cent of the 133 groups studied—enforced incest taboos which included a great number of relatives. These authors further stated that "among all peoples both partners in a mateship are forbidden to form sexual liaison with their own offspring." This prohibition characterizes every culture. Sibling incest is also generally condemned.

Similarly, Kinsey et al. reported that incest cases were so rare in the sample population they studied that "it would be misleading to suggest where the highest incidences lie."

Incest prohibitions are not inborn. Ford and Beach maintained that "social rules against intercourse with close relatives reflect cultural, rather than physiological, or biological, tendencies." In fact, Freud had advanced a similar view of the origins of the incest taboo many years earlier:

Thus the view which explains the horror of incest as an innate instinct must be abandoned. Nor can anything more favorable be said of another, widely-held explanation of the law against incest, according to which primitive peoples noticed at an early date the dangers with which their race was threatened by inbreeding and for that reason deliberately adopted the prohibition. There are a host of objections to this theory. ... Not only must the prohibition against incest be older than any domestication of animals which might have enabled men to observe the effects of inbreeding upon racial characters, but even today the detrimental results of inbreeding are not established with certainty and cannot easily be demonstrated in man.

He went on to say:

Respect for this barrier [incest] is essentially a cultural demand made by society. Society must defend itself against the danger that the interest it needs for the establishment of higher social units may be swallowed up by the family.

Etiology. Normal development implies the conquest of oedipal strivings, which are then replaced by adult sexuality. In contrast, the neurotic mind is characterized by its tendency to cling to oedipal wishes. In other words, because the Oedipus complex has not been resolved, strong incestuous wishes remain operative. These incestuous wishes rarely find direct genital expression because of the strong social taboos against such acts. However, their mere presence has serious implications for psychosexual development. Thus, in a paper written in 1905, Freud noted:

The closer one comes to the deeper disturbances of psychosexual development, the more unmistakably the importance of incestuous object-choice emerges. In psychoneurotics a large portion of the whole of their psychosexual activity in finding an object remains in the unconscious as a result of their repudiation of sexuality. . . . In cases in which someone who has previously been healthy falls ill after an unhappy experience in love it is also possible to show with certainty that the mechanism of his illness consists in a turning-back of his libido on to those whom he preferred in his infancy.

Similarly, the individual may manifest a wide range of distortions and deviations in his sexual behavior as a defense against his strong unconscious incestuous desires. All sexual object relationships may be inhibited and weakened as a protection against the breakthrough of these drives.

It follows, then, that the acting out of the Oedipus complex by actually breaking the incest barrier is a regressive phenomenon which implies a serious defect in ego development. Thus, in schizophrenia, for example, the desire for incestuous intercourse is frequently expressed openly, and attempts are made to act on this desire.

Clinical description. We recognize incestuous feelings as fairly common phenomena in clinical practice. Many fathers are in love with their daughters; many brothers are very much attached to their sisters; many mothers love their sons. But most neurotics have erected strong defenses against such feelings, so that the most innocent expressions of affection may give rise to anxiety.

Clinical studies show that in cases where father-daughter incest has actually been consummated, the daughters have ranged in age from 6 to 17; most often, the eldest daughter is chosen as the sexual object. The fathers in these cases maintain a facade of patriarchal competence, which hides deep feelings of uncertainty with regard to their masculinity. Sometimes they are alcoholics or drug addicts. The mothers in such cases have relegated their position as the central female of the household to their daughters.

Sibling incest, as part of exploratory sex play, has been reported fairly frequently in preadolescence. When it occurs in early adolescence, it has more serious implications as indicative of intense penis envy in girls or an acting out of the boy's oedipal wish for genital union with the mother.

Mother-son incest is rare. In known cases, the fathers were ineffective, and the mothers were unusually passive. For the most part, the sons were preadolescent at the time of the consummation of the incest. Follow-up studies have shown that in later years, these sons became "extroverts," affected attitudes of omnipotence, and were unable to sustain a marital relationship.

Prognosis. Because the breakthrough of incestuous drives implies the serious lack of impulse control which typically precedes the onset of psychosis, the prognosis for adult patients in this category is generally poor. The prognosis is more favorable for younger patients, however.

Management. Ideally, younger patients in this category should be referred to residential treatment settings (rather than foster homes, for example). Foster home placement will, in all likelihood, produce attempts to seduce their foster parents, since no effort has been made to deal with the underlying problem. On the other hand, if such patients live with a group of other patients of the same sex and approximately the same age, and proper treatment facilities are available to them, the intensity of their oedipal strivings may diminish.

Pedophilia

Definition. The pedophile requires the cooperation of a child partner of the same or opposite sex in order to achieve sexual gratification. (In this context, the term "child" is understood to include the sexually immature adolescent.)

Epidemiology. It is well known that in Ancient Greece homosexual pedophilia was common. However, for obvious reasons, precise statistics as to the current incidence of pedophilia are difficult to obtain. While police records of parents' complaints that their child has been molested do provide some clue as to the prevalence of this sexual deviation, other factors must be taken into consideration. For example, the adolescent "victim" in such a complaint may, in fact, have concealed his (or her) age, and behaved in a deliberately seductive manner. On the other hand, the practice of fellatio and masturbation of male infants by their nurses and mothers is not rare. Furthermore, children lend themselves to fondling and to lap sitting, which may be accompanied by friction with adult genitalia.

Etiology. The pedophile avoids coitus with an adult love object because of his overwhelming castration anxiety; instead, he is attracted to children who do not elicit the same anxiety because they are weak and approachable. The pedophile's fear of castration also reinforces his narcissism. It is generally agreed that love for children is usually based on such narcissistic tendencies. More specifically, unconsciously, the pedophile is in love with himself as a child, and he treats his child love objects in the same

way he would have liked to have been treated as a child.

Like the homosexual, the pedophile identifies with his frustrating mother. However, the homosexual identifies with his mother's love for men. On the other hand, the pedophile is more narcissistic than feminine. Having identified with his mother, he behaves as he had previously wished his mother to behave toward him. Consequently, he chooses as love objects young men, or boys, who remind him of himself.

Clinical description. Freud described pedophilia as the perversion of the "weak and impotent," and clinical evidence has shown that most male pedophiles are partially or totally impotent. Usually, their sexual activity consists of masturbatory and exhibitionistic behavior.

The pedophile's attempt to penetrate an infant or very young child may, of course, cause physical damage. However, the role of the child should not be minimized. For instance, Greenacre has described the youngster's seductive attitude in provoking prepuberty sexual trauma to herself. As mentioned above, when the immaturity of the young person is concealed, and her seductiveness plays a major role, a diagnosis of pedophilia would be questioned. Rather, one might be tempted to speculate that the behavior of such a child, in acting out her oedipal strivings, was more indicative of the presence of psychopathology than the pedophile's response to her actions.

Pedophilia is similar to other sexual deviations, particularly zoophilia and sadomasochism, as well as homosexuality and incest. However, zoophilia, which refers to sexual excitation by stroking and fondling animals appears to be more fetishistic and sadistic in quality; pedophilia is masochistic and bears no resemblance to fetishism. The pedophile, although he engages in elaborate secret, hide and seek games, usually does get caught. Exposure of his "naughty" behavior, and punishment by the authoritative adult, gratifies the pedophile's narcissistic identification with the child.

Prognosis. The masochism of the pedophile makes successful psychotherapy difficult. A habitual homosexual pedophile's intractability is epitomized in the statement quoted by Rubinstein: "It's worth going to prison for."

Management. Pedophilia must be differentiated from a primary disorder such as organic brain syndrome. A toxic condition or senility also may release pedophilic impulses and may be treated as such.

Once the diagnosis has been clearly established, attention to the masochistic component is essential in any form of therapy. If the pedophile's basic personality problem is a neurotic distortion, then psychoanalysis would be the treatment of choice.

Bestiality

Definition. The human being who engages in bestiality achieves sexual gratification by having intercourse with a living animal.

Epidemiology. During periods of history, and in some cultures, bestiality, or zoorasty, received religious sanction. In the last days of the Roman Empire, for example, bestiality was practiced quite openly. In Kinsey's sampling, however, intercourse with animals was the least frequent form of human sexual behavior. He further reported that it was most common in the preadolescent years (before ejaculation) and decreased markedly after young adulthood. Rural living was found to be a significant factor in the incidence of bestiality. One third of the males who lived in rural areas, and were in the upper educational level, according to Kinsey, had had sexual intercourse with an animal to the point of orgasm.

Etiology. The central consideration, as in other sexual deviations, is the reaction against the castration fear. The animal, in toto, symbolizes the phallus and asserts its presence and mastery. Identification with the small animal, in toto, gratifies the wish for tender, loving care which the helpless animal (child) requires. On the other hand, a dangerous or benevolent large animal permits identification with the parental role in the child-parent relationship.

Partial aspects of the animal, such as the hind quarters—symbolizing the male genitalia, breasts, and buttocks—quell castration anxiety by permitting regressive forms of sexual arousal. Arousal through observation of copulating animals enforces identification with the prowess of the animal.

Of major significance in bestiality is the fact that animals don't talk. The human is safe not only from rejection, but also from fear of retaliation.

Isolation from other humans has etiological and diagnostic implications, particularly with respect to schizoid personalities, who have great anxiety in human relationships. Infrahuman object relationships provide an opportunity for the mastery of such anxiety. A severely phobic, schizophrenic young virgin, dominated by an aggressive mother, was preoccupied with sadistic fantasies. She "solved" her sexual conflicts by training her large, ferocious dog to perform cunnilingus.

Clinical description. A wide variety of domestic animals have been used in bestiality. Among families who own pets, such as dogs, an excessively emotional relationship with the animal may exist. Sometimes a dog may be observed vigorously rubbing its genitalia against the leg of a child or an adolescent in the family, or even an adult. The acquiescent human's role in this masturbation is "passive," denied, sparing of the self. The other (the animal) is doing it. An active role may be played when the human masturbates the animal by rubbing its genitalia. However, this activity requires a mastering of the anxiety which surrounds

the forbidden masturbatory behavior by rationalizing it as experimentation with another.

Rubbing the human genitals against the fur of the animal is, of course, a more direct form of masturbation. Fellatio and cunnilingus are not infrequent techniques of bestiality. Dogs, cats, and even calves have been trained to lap human genitalia.

Prognosis. Farm boys are apt to overcome their bestiality when they are no longer as isolated socially and are able to establish sexual relationships with girls. Similarly, for adolescents in general, the use of an animal as a transitional object in avoidance of incestuous and masturbation conflicts is usually relinquished when success in socialization with peers of the opposite sex occurs.

Management. When the bestiality persists into adulthood, the essential diagnosis should be established. If there is an underlying schizophrenic process operating, therapy should be directed at relieving that illness. For so-called borderline personality disorders, psychoanalytic psychotherapy or psychoanalysis, where possible, is the treatment of choice.

Suggested Cross References

In this section the etiology and treatment of sexual deviations are presented from the viewpoint of classical psychoanalytic theory. For an alternate conceptualization of sexually deviant behavior see Bieber's introduction to the subject of sexual deviations (Section 26.2) as well as his discussion on homosexuality (Section 26.3). Further information regarding sexual development according to classical psychoanalytic theory may be found in Chapter 6, while other viewpoints on this topic are contained in the chapters and sections dealing with the other psychodynamic and psychological theories of personality and psychopathology presented in Area C. See Section 5.7 for a discussion of normal sexuality. For a more detailed discussion of psychoanalysis and psychotherapy, see Section 34.1 in Area G, on psychiatric treatment. See also Section 41.6 on sexual deviations in children.

Chapter 27

Personality Disorders. III: Sociopathic Type: The Addictions

27.1 ADDICTIONS. I: OPIOID ADDICTION

ABRAHAM WIKLER, M.D.

Definition

In the *Diagnostic and Statistical Manual* of the American Psychiatric Association, drug addiction is said to be symptomatic of a personality disorder and is classified under sociopathic personality disturbance but is not otherwise defined. The wisdom of such forbearance becomes apparent when one considers the various usages of terms—such as addiction, habituation, physical dependence, psychic dependence, and emotional dependence—that abound in the literature.

In the strict pharmacological sense, addiction is synonymous with physical dependence and refers to a state produced by repeated administration of certain drugs. When the drug is withdrawn abruptly, a train of transient physiological disturbances (abstinence syndrome) occurs that is specific for the drug in question and other agents with similar pharmacological actions. Traditionally, the term “habituation” or “psychic dependence” has been reserved for reference to compulsive drug use without development of physical dependence, with the obviously absurd implication that addiction and habituation are mutually exclusive.

In an attempt to resolve such ambiguities, the World Health Organization (W.H.O.) Expert Committee on Addiction-Producing Drugs has recently proposed to replace the terms “drug addiction” and “drug habituation” with the new term, “drug dependence,” which is defined as “a state arising from repeated administration of a drug on a periodic or continuous basis. Its characteristics will vary with the agent involved, and this must be made clear by designating the particular type of drug dependence in each specific case—for example, drug dependence of

morphine type, of cocaine type, of cannabis type, of barbiturate type, of amphetamine type, etc.”

Following the suggestion of Professor George H. Acheson, the term “opioid” will be used in this section to refer to any compound, natural or synthetic, with morphine-like properties, thereby avoiding the ambiguities of such terms as “opiate”—which refers to derivatives of opium, including those, like papaverine, that are devoid of analgesic actions—and “narcotic,” which in some usages refers to the general anesthetics.

Examination of these specific W.H.O. definitions reveals that common to all is a desire or need to continue taking the drug—in other words, compulsive drug use or habituation. In the cases of morphine and barbiturates, physical dependence is also listed as a characteristic of drug dependence (physical dependence does not develop on repeated administration of cocaine, cannabis products, or amphetamine-like compounds, except that transient hypersomnia may occur after abrupt withdrawal of amphetamine or its analogues), but the W.H.O. definitions make no attempt to relate physical dependence and habituation. Actually the term “drug habituation” would suffice to designate the general problem of abuse of drugs of any kind. There is evidence that under certain conditions the development of physical dependence provides a powerful basis for reinforcement of habituation. Therefore, other factors being equal, persons who abuse drugs of the morphine type are more likely to become habituated. Hence, addiction in the strict pharmacological sense is an important factor that must be considered from a practical as well as a theoretical standpoint in any discussion of the problem of abuse of drugs of this type. Accordingly, the most general appellation for persons who abuse opioids would be “opioid habitués” (who may or may not also be “addicted”). But the term “opioid habitués” is not in general acceptance, and so the words “addiction” and “addicts” will be used here in the loose but popular sense, referring to abusers of opioids in gen-

eral, with reliance on the context to clarify the particular issues discussed.

The term "abuse" implies that self-administration of the drug in question has harmful effects on the individual, society, or both. As stated by the W.H.O. committee, "With morphine, the harm to the individual is in the main indirect, arising from preoccupation with drug-taking; personal neglect, malnutrition, and infection are frequent consequences. For society also, the harm may be related to the preoccupation of the individual with drug-taking; disruption of interpersonal relationships, economic loss, and crimes against property are frequent consequences."

Community Laws and Attitudes

Though the dangers as well as the therapeutic benefits of opium were mentioned by some observers much earlier, it appears that it was the situation in China during the latter part of the 19th century that first aroused concern on an international scale. As cited by Kolb, it was estimated that there were 15 million opium smokers in that country in 1906—and as many in 1937, in spite of drastic efforts to curb the practice, including infliction of the death penalty in some cases. International efforts to curb the non-medical uses of opium and its derivatives and, more recently, synthetic opioids, began with the Hague International Opium Convention of 1912, which was followed by the Geneva Convention of 1925 and subsequent conventions and protocols in 1931, 1936, and 1948. These international agreements, monitored by various bodies—such as the Permanent Central Opium Board, the Drug Supervisory Body, the Commission on Narcotic Drugs of the United Nations Economic and Social Council, the Expert Committee on Addiction-Producing Drugs of the World Health Organization, and the Division of Narcotic Drugs of the United Nations—provide for limitation of production, importation, and exportation of opium, coca leaves, and cannabis products and control of the manufacture, sale, and dispensation of opioids with significant physical dependence-producing properties.

Federal laws. According to Isbell, the three major sources of the opioid addiction problem in the United States were: (1) symptomatic treatment with nostrums containing opium or, later, heroin, which was first thought to be nonaddicting; (2) the Civil War, with its aftermath of disabled veterans with painful conditions who were treated with morphine by the then new method of hypodermic injection; and (3) the importation of Chinese laborers to the West Coast between 1852 and 1870, among whom opium smoking was fairly common—a practice that was soon emulated by antisocial elements in the non-Chinese population. The last factor in particular seems to have given rise to the popular association of opioid addiction with crime and other vices. Though figures are unreliable, Kolb reported an estimate up to 264,000 addicts in the United States at the turn of the century, when the

population of the country as a whole was probably about 76 million.

Partly because of public indignation and partly in fulfillment of the obligations of the United States Government under the Hague Convention of 1912, the Congress passed the Harrison Narcotic Act in 1914. Though primarily intended to control the importation, manufacture, and distribution of opium and its derivatives and coca leaves and its derivatives, the Harrison Act also specified that physicians could prescribe or dispense such drugs only in the course of their professional practice and only to bona fide patients.

Subsequent laws have provided similar controls on synthetic opioids and marihuana, and penalties for violation of all of these laws have become increasingly severe. Public Law 728, passed in 1956, provides that illegal possession of opioids or marihuana is punishable by a fine of \$20,000 and imprisonment for 2 to 10 years on the first offense, 5 to 20 years on the second offense, and 10 to 40 years on the third offense; parole and probation are possible only on the first offense. Sale of such drugs is punishable by even more severe penalties, and sale of heroin to a person under 18 years of age is punishable by a fine of \$20,000 and imprisonment for 10 years to life or by death at the discretion of the jury. However, civil commitment, analogous to commitment for mental disorders, is possible in Illinois, California, New York, and the District of Columbia, under certain conditions.

Clinics. The immediate effect of the Harrison Act, with its implied prohibition (so interpreted by the Federal Bureau of Narcotics and often, though not always, upheld by the courts) of dispensation of morphine to addicts solely for the purpose of maintaining their addiction, was to channel large numbers of addicts into the illicit narcotic market. To deal with this problem, clinics were set up in a number of states for the purpose of curing addicts by dispensation of morphine in progressively decreasing amounts on an ambulatory basis. These clinics predominantly failed, and in 1921 the American Medical Association condemned ambulatory treatment of drug addiction in any form, including that practiced at clinics. As a result, the clinics were closed shortly afterward by the Treasury Department.

In 1929, Congress authorized the establishment of Federal hospital facilities for treatment of addicts and research on drug addiction. Accordingly, the United States Public Health Service Hospital in Lexington, Kentucky, was opened in 1935, and beds for addicts were made available at the United States Public Health Service Hospital in Fort Worth, Texas, a few years later.

In 1955, the New York Academy of Medicine, objecting strongly to what they regarded as the excessively punitive character of the laws concerning addicts in the United States, proposed the reestablishment of clinics for the treatment of addicts with

special safeguards to minimize self-administration and diversion of drugs for purposes other than that of cure. Although agreeing with the New York Academy of Medicine to the extent of recommending more widespread use of civil commitment of addicts, committees appointed by the American Medical Association and the American Bar Association did not favor reestablishment of clinics.

Medical code for addicts. More recently, a joint report of the American Medical Association's Council on Mental Health and the National Research Council, Committee on Addiction and Narcotics for the National Academy of Sciences, recommended a code on the use of opioid drugs in the medical management of opioid addicts. This code has been declared acceptable to the Federal Bureau of Narcotics.

The essential features of this report are as follows. Although maintenance of addicts on stable dosage levels of opioids and ambulatory clinic plans for the withdrawal of opioids from addicts are considered generally inadequate and medically unsound, bona fide research on such treatments should not be obstructed. Ambulatory maintenance can be considered ethical medical practice if, after consultation with one or more other physicians, it is agreed that withdrawal would be hazardous to life or that continued drug administration is necessary for treatment of a chronic or terminal painful condition, other than the drug addiction itself, for which no other mode of treatment is feasible. Under exceptional circumstances, ambulatory withdrawal treatment may be undertaken by a physician with special skill and experience in the management of addicted patients, provided that in consultation with other physicians it has been decided that ambulatory withdrawal is, in fact, indicated. Otherwise, it is recommended that withdrawal be carried out in a drug-free environment in specialized wards of installations for narcotic addicts. However, in dealing with a relatively small number of patients who have been well evaluated, a physician with special skill and experience in the treatment of addicted patients may carry out the withdrawal procedure in the psychiatric wards of general hospitals, in a properly selected ward of a public or private mental hospital without specialized units, or in certain general hospital wards. Addicted patients awaiting admission to a treatment facility may be treated by a physician on an out-patient basis in daily visits for not more than 10 days to 2 weeks.

The British system. In recent years, there has been much public debate in the United States about the so-called British system. In point of fact, the importation, manufacture, and sale of opioids are strictly regulated by law in Great Britain, and, at least until very recently, the opioid addiction problem there has always been very small. The total number of addicts known to the Home Office was 454 in 1960. The mode of treatment of addicts, including long term

maintenance on opioids in special cases, has been left to the judgment of the practising physician, and no government clinics have existed in Great Britain where opioids may be dispensed to "registered" addicts for the maintenance of their addiction. However, because of an unprecedented increase in the number of young addicts during the past few years, the situation is now being reappraised by a governmental commission, and some changes in the British system may result from this inquiry.

Prevalence and Incidence

The most reliable source of information on the prevalence and incidence of persons with opioid addictions in the United States is that supplied by the Federal Bureau of Narcotics, which maintains a file of active addicts. This list includes the names of persons arrested and charged with a violation of narcotics laws, obtained from police records throughout the country. After they are reported initially, such names are kept on the active list for 5 years and are then placed in an inactive list if they have not been reported again during that period. Since 1955, as reported in the Bureau of Narcotics' 1963 report, the total number of active addicts included in the list for any year has been less than 50,000 (48,535 in 1963), despite additions to the list of some 7,000 to 9,000 names each year—a phenomenon that suggests that an approximately equal number of names are dropped from the active list each year.

The ratio of males to females in the list is generally about 3 or 4 to 1 and somewhat more than half of the total number are Negroes, with Puerto Ricans and Mexicans constituting substantial minorities within the Caucasian group. Slightly more than half are between 21 and 30 years of age, and about a third are 31 to 40. Juveniles (under 20 years of age) constitute somewhat less than 4 per cent of the total; about 12 per cent are over 40. In 1963, 48.3 per cent were reported from New York State, 14.6 per cent from Illinois, 14 per cent from California, 3.6 per cent from Michigan, and the remainder from all other states. During recent years, the vast majority of all addicts have used heroin primarily, with morphine, meperidine, and other opioids following in that order.

The predominance of Negroes in the country's addict population is a relatively new phenomenon, the great majority of addicts in the 1930's having been Caucasian. Also there has been an increasing concentration of addicts in large metropolitan areas, contrasting with a more even distribution in rural (predominantly Southern) and metropolitan areas in earlier years. As judged by the characteristics of the patient population at the United States Public Health Service Hospital in Lexington, Kentucky, from 1935 up to the present time, other changes apparently have occurred. The typical addict in 1936 was a white male prisoner, 38 years of age, who had been given a 2-year sentence for illegal sale of narcotics, who suffered from some

chronic disease such as arthritis, tuberculosis, or asthma, and, who did not become addicted to morphine until the age of 27. In 1955 the typical addict was a Negro male voluntary patient in his twenties who began the use of heroin at about 20 years of age and who was relatively well physically.

Sociological and criminological aspects. The majority of present day addicts are derived from the most depressed districts in metropolitan slum areas, which are differentiated from more favorable environments not only by their greater economic privation but also by greater availability of illicit drugs, laxness of social controls, and greater prevalence of psychopathic attitudes toward law and order and goals in life. In such districts, relationships between parents and between parents and children are likely to be much more disturbed than in the typical middle class American family. Particularly in the Negro population of such districts, the mother is likely to be the breadwinner; the father, if he is present at all, is chronically unemployed. Under such circumstances, it is not surprising that delinquency is common; however, the relationship between addiction and delinquency is by no means a simple one. Sociological studies by Chein et al. and Clausen have shown that there are areas with high delinquency but low narcotic addiction rates and that, in areas where both rates are high, crimes against property tend to be greater, and crimes against persons tend to be smaller in proportionate numbers.

These and other data seem to suggest that, although narcotic addiction per se does not increase criminal activity in general, except for narcotics laws offenses, it does promote crimes directed toward financial gain. Even this inference, however, is subject to doubt because it is not possible to estimate the number of criminal acts and the types of criminal acts that would have been committed by addicts had they not become addicted to opioids. However, the salient fact remains that only a minority of slum dwellers become opioid addicts.

Sociological factors, although undoubtedly contributing greatly to the genesis of addiction, are not sufficient to explain it. Currently, it is assumed that personality factors, interacting with sociological and pharmacological factors, constitute the major determinants of addiction.

Pharmacology

Chemical structure. Opium, which is prepared from the sap of the poppy seed capsule, *Papaver somniferum*, contains two classes of alkaloids, the phenanthrene and the benzylisoquinoline, of which only the former is of interest here. Included among the phenanthrene alkaloids are morphine and codeine, the former constituting 10 per cent and the latter 0.5 per cent by weight of opium itself. The chemical structures of morphine and some of its derivatives are shown in Figure 1. Attention is directed particu-

FIGURE 1. Opioids with intact phenanthrene nucleus.

larly to the hydroxy groups on carbon 3 (phenolic) and on carbon 6 (alcoholic), alterations of which alter the pharmacological properties of morphine considerably.

In general, alterations of the phenolic hydroxy group weaken analgesic activity, and alterations of the alcoholic hydroxy group augment analgesic activity. When subcutaneously administered doses are compared for analgesic activity, codeine, obtained by methylation of the phenolic hydroxy group, is only $\frac{1}{12}$ as potent, and dihydromorphinone (Dilaudid), obtained by removal of the hydrogen on the alcoholic hydroxyl, is 5 times as potent as morphine. Heroin, formed by acetylation of both hydroxy groups, is between 2 and 3 times as potent as morphine. Other potent analgesics derived synthetically from morphine include members of the morphinan series, such as levorphanol (Levo-Dromoran), and of the benzomorphan series, such as phenazocine. In contrast, certain substitutions on the nitrogen atom produce compounds that, though possessing analgesic properties, are powerful morphine antagonists; examples of these are nalorphine (Nalline), levallorphan (Lorfan), and cyclazocine (Figure 2). In addition to these agents, there are a number of synthetic compounds with morphine-like actions, the chemical structures of which bear little resemblance to that of morphine (Figure 3). Of these, methadone (Dolophine) is

roughly equivalent to morphine in analgesic activity, dextropropoxyphene (Darvon) is roughly equivalent to codeine, and meperidine (Demerol) is about $\frac{1}{8}$ as potent as morphine.

Metabolism. Most of an injected single dose of morphine appears in the urine within 24 hours, the remainder appearing in the feces (from bile) later. In its excreted form, morphine appears as the conjugated glucuronide, though free morphine is also detectable. In addition to conjugation with glucuronic acid, detoxification of morphine is also accomplished by *N*-demethylation in animals; but the importance of this pathway in man has not yet been established. Heroin is deacetylated and subsequently metabolized in the same manner as morphine. Other opioids are likewise detoxified by conjugation, but the details of their metabolism have not been fully investigated.

Sites and modes of action. The effects of morphine that are of major clinical interest are those mediated by actions on the central nervous system, though certain of its side effects are produced by actions on other structures, such as flushing and itching of the skin (especially on intravenous injection) by release of histamine and constipation by decrease of propulsive movements of the intestines coupled with spasmogenic actions on contractile movements of the intestinal tract and on sphincters.

Within the central nervous system, morphine ex-

erts a combination of depressant and excitant actions at all levels of the neuraxis. In the chronic spinal dog (unanesthetized dog with complete transection of the spinal cord at the lower cervical or midthoracic level made under anesthesia months or years previously), morphine depresses the ipsilateral flexor and crossed extensor reflexes, has little effect on the knee jerk, and enhances the ipsilateral extensor thrust. This pattern of effects suggests that morphine has a selective depressant action on conduction within chains of internuncial neurons arranged in reverberating circuits, coupled with either direct excitation or release from inhibition of motoneurons. However, this pattern is more difficult to detect at higher and more complex levels of integration in the central nervous system. In addition, morphine affects spinal reflexes through augmentation of supraspinal inhibition, since the depressant effects of morphine on the tail flick in the rat and on the skin twitch in the dog are greater in the intact than in the spinal animal.

At the medullary level, morphine depresses the sensitivity of the respiratory center to carbon dioxide but enhances the sensitivity of sinoaortic chemoreceptors and vagal stretch receptor respiratory reflexes. Morphine bradycardia appears to be produced by direct central vagal stimulation and vomiting, by stimulation of the chemoreceptor trigger zone.

In the midbrain, morphine enhances the sensitivity of oculomotor parasympathetic neurons to light stimuli and probably also exerts a tonic excitant effect on these structures, since morphine constricts the pupil even in total darkness.

The actions of morphine on the hypothalamus are quite complex. Sham rage in decorticated cats and dogs is markedly reduced by morphine when such reactions are elicited by sensory stimulation but not on direct stimulation of the hypothalamus. Release of antidiuretic hormone appears to be due to a direct stimulant action of morphine on the hypothalamus. In the rat, morphine causes release of adrenocorticotrophic hormone (ACTH) from the pituitary gland through a direct stimulation of the hypothalamus but blocks release of ACTH by histamine or vasopressin. In man, the effects of single doses of morphine on ACTH release are variable, but ACTH production is depressed during chronic administration of the drug. In the dog, morphine sensitizes the anterior hypothalamus both to direct heat and to impulses arising from heated skin, thereby producing hypothermia. In animals, morphine hyperglycemia is produced by release of epinephrine consequent to a direct or indirect excitant action of the drug on the posterior hypothalamus.

In the rat and the rabbit, morphine elevates the threshold of excitation of the ascending reticular activating system. In the rabbit, it also enhances recruiting responses evoked by stimulation of thalamic intralaminar nuclei and induces spiking activity in the hippocampus. In man, single analgesic doses of morphine produce little change in the surface electroencephalogram (EEG), but chronic administration of the drug is accompanied by increasing synchronization of the EEG.

Because of certain similarities between the effects of analgesic doses of morphine and of bilateral prefrontal lobotomy on pain (reduction of the affective reaction without impairment of discrimination of the noxious stimulus), it has been inferred that morphine exerts a depressant action on conduction in frontothalamic pathways; however, direct evidence of such an action is lacking. Morphine appears to have no action on direct sensory pathways from peripheral nerves to the cerebral cortex mediated by the thalamic relay nuclei; however, it has been reported that in the cat morphine and meperidine selectively repress responses in the paralemniscal and ventral tegmental areas of the midbrain evoked by electrical stimulation of a tibial nerve.

Bearing on the reasons for the selectivity of mor-

phine action on the central nervous system is current research on the interaction of morphine with neurohumoral substances. It has long been known that morphine inhibits cholinesterase, but this action does not appear to be related to its analgesic effect. More recently it has been shown that morphine reduces the resting output of acetylcholine and the output from postganglionic cholinergic nerve endings when they are stimulated, that morphine inhibits the release of sympathetic transmitter substance from postganglionic endings, and that repeated administration of morphine results in an increase in brain concentrations of norepinephrine. *In vitro*, morphine does not affect respiratory activity at rest but does inhibit the increased oxygen consumption produced by stimulation with potassium chloride.

Tolerance and physical dependence. When a fixed dose of morphine is injected at regular and frequent intervals, certain of its effects, predominantly depressant, decrease progressively in intensity, and a larger dose is necessary to produce effects comparable in magnitude to the original ones observed. Concomitant with such increasing tolerance is the development of physical dependence or pharmacogenic dependence, which becomes manifest when the drug is withdrawn abruptly. In general, the abstinence syndrome that ensues under such circumstances is characterized by temporary hyperactivity of those functions that were previously depressed by morphine. These phenomena can be demonstrated not only in man but also in intact monkeys, dogs, and rats, in long surviving decorticated dogs, in chronic spinal dogs (also in a chronic spinal man), and even in unicellular organisms and tissue cultures.

The rapidity with which tolerance and physical dependence develop and the intensity of the dependence are, within limits, directly related to the frequency and duration of administration of morphine and the daily dose level that is finally attained before the drug is discontinued abruptly. In man, clear cut though mild abstinence phenomena can be demonstrated after abrupt withdrawal of morphine following a 2-week period of administration of 15 to 20 mg. of the drug four times daily. More intense abstinence phenomena can be precipitated much earlier during chronic morphine intoxication by injection of a single small dose of a morphine antagonist, such as nalorphine or levallorphan. In man, abstinence phenomena have been demonstrated with this technique after administration of 15 mg. of morphine or equivalent doses of heroin or methadone four times daily for 2 to 3 days. In the dog, definite evidence of tolerance can be seen during a continuous 8-hour intravenous infusion of a moderate dose of morphine, and at the end of that period abstinence phenomena can be precipitated by a single injection of nalorphine.

Studies by Martin and Eades on reflex and other responses in intact and in chronic spinal dogs during a continuous infusion of morphine and after multiple

daily subcutaneous doses for several weeks indicate that at least three mechanisms are involved in the genesis of tolerance and physical dependence: (1) relatively rapid though only partial restoration of autonomic functioning through responses of homeostatic systems to the abnormal conditions—hypercapnia, hypothermia, etc.—created by the depressant effects of the drug; (2) somewhat more slowly developing recruitment of auxiliary (normally redundant) neural circuits for the maintenance of both autonomic and somatic functions; and (3) still slower development of latent hyperexcitability of those neural circuits, autonomic and somatic, on which morphine exerts depressant effects. The first mechanism and to some extent the second appear to account for acute tolerance. The second and third appear to account for chronic tolerance in the intact animal and in the chronic spinal dog above the level of cord transection. Below the level of cord transection, acute tolerance is minimal, and chronic tolerance—the capacity for which is very great—appears to be generated mainly by the third mechanism. Although the abstinence syndromes (indicative of physical dependence) precipitated by a single dose of nalorphine in either the acutely or chronically tolerant state are very similar, that in the former state is produced by resensitization of homeostatic systems, which then respond to the abnormal internal milieu, thereby producing autonomic overactivity until the internal milieu is normalized; in the latter state, nalorphine unmasks the latent neural hyperexcitability, with consequent evocation of autonomic and somatic overactivity that persists until the latent hyperexcitability is dissipated.

Another theory of tolerance and physical dependence as detailed by Jaffe and Sharpless is modeled after the well known phenomenon of denervation supersensitization in peripheral structures, such as the nictitating membrane of the cat. According to this theory, decrease in activity of a neural aggregate over a prolonged period of time results in supersensitization of the same neural aggregate to all neurohumors that normally could excite it; when activity in the neural aggregate is restored, as by withdrawal of the depressant drug, the supersensitized neural aggregate responds excessively to such neurohumors, thereby producing an abstinence syndrome, which declines in intensity over a time course paralleling the decline in pharmacological supersensitivity.

The development of progressively increasing latent hyperexcitability or supersensitization of the central nervous system during chronic administration of morphine may be viewed as a counter-adaptation to the depressant effects of this drug. All the data strongly suggest that such counter-adaptation is developed at a cellular level, but little is known about the biochemical changes involved. Cortical slices from brains of rats treated with morphine daily for 1 week exhibit tolerance to the depressant effects of morphine on oxygen consumption stimulated by potassium chlo-

ride, but the enzymatic processes involved have not been elucidated. In rats, the development of tolerance to morphine is associated with progressive decrease in the capacity of the liver to *N*-demethylate this drug—a phenomenon suggesting that a decreased response to narcotic drugs on repeated administration may develop as a result of unavailability of receptor sites due to inactivation of the latter through continuous interaction with opioids. It has also been suggested by Collier that tolerance and physical dependence may be due to induction of new receptors that, together with the normal number of receptors, become available to neurohumors when morphine is discontinued, thereby giving rise to abnormally intense activation of the cell (abstinence syndrome) until the newly induced receptors are eliminated.

Whatever the mechanisms underlying cellular counter-adaptation to the effects of morphine may be, its complete dissipation apparently requires much more time than has been generally recognized. In man, complete stabilization of certain physiological variables is not achieved for up to 6 months following withdrawal of morphine, and in rats, as shown by Martin et al., small differences between control animals and animals previously addicted to morphine persisted for at least 6 months after withdrawal of morphine in the latter. In rats it has also been demonstrated that at least one manifestation of the morphine withdrawal syndrome can become conditioned to environmental stimuli in the classical Pavlovian manner—a phenomenon that may play a role in relapse.

Signs and Symptoms

Acute intoxication. In man, the effects of a single analgesic dose of morphine or other opioid appear to depend on a number of factors, including the subject's previous experience with the drug, certain as yet unidentified aspects of his personality, the presence or absence of pain, and the setting in which the drug is administered.

In experimental subjects without pain and without previous histories of narcotic addiction, morphine often produces dysphoria attributable to nausea, giddiness, and a subjective sense of mental clouding, although psychomotor performance on objective tests is impaired little or not at all except when speed is important.

In subjects with pain, morphine produces a negative euphoria ascribable to relief of pain or apprehension.

In certain individuals without pain and uniformly in subjects with previous histories of narcotic addiction but who are nontolerant to morphine, a single injection of the drug commonly produces a state that is reported by the subject to be unusually pleasant (positive euphoria), even though he may vomit and exhibit an alarming pallor to the observer. If undisturbed, such subjects may "go on the nod"—that

is, they may exhibit a state of semisomnolence from which they can be aroused easily—or they may exhibit “driving”—a display of unaccustomed energy in carrying out assigned duties. The sensorium remains intact, and skilled acts are not grossly impaired.

Pain perception thresholds (radiant heat to forehead, electrostimulation of tooth pulp) are not altered in a consistent manner by morphine, but analgesic doses of the drug do reduce significantly the disruptive effects on discrimination or on reaction time produced by anticipation of painful stimulation—an effect not produced by even a large dose (250 mg.) of pentobarbital. Probably related to this effect of morphine on pain-anticipatory anxiety is the finding reported by Jones et al. that single doses of morphine reduce the increment in basal skin conduction that develops during classical conditioning of electrodermal responses to electric shock stimuli.

More generally, morphine appears to reduce the range of change in psychomotor performance effected by variation of incentive level; pentobarbital increases it. At least under experimental conditions, “postaddicts” do not report increased fantasies after parenteral administration of morphine; on the Rorschach test, however, the drug has been reported to reduce constriction and to increase fantasy and inner living.

The effects of morphine on sexual experience and behavior are rather complex. Particularly on intravenous injection, many postaddicts report sensations akin to orgasm, which, however, are localized in the abdomen. Sexual desire is not increased, although male potency may be augmented by delay of orgasm.

Flushing and itching of the skin are also common after intravenous injection of morphine. Other effects of single doses of morphine, regardless of route of administration, are pupillary constriction, depression of respiratory rate, slight lowering of body temperature, and spasm of smooth muscle sphincters. In general, the effects of a single dose of morphine reach peak intensity about 20 minutes after intravenous and 1 hour after subcutaneous injection and persist with declining intensity for 4 to 6 hours, after which postaddicts report a “let down” feeling.

Comparative effects. Although heroin is more widely used by addicts in the United States than morphine, a careful study by Martin and Fraser of the subjective and objective effects of these two drugs has failed to reveal the basis for such preference. When administered intravenously in equipotent doses (1.80 to 2.66 mg. of morphine sulfate = 1 mg. of heroin), the time courses of action of the two drugs are quite comparable, as are reports of euphoria, ambition, nervousness, relaxation, drowsiness, and sleepiness. Nevertheless, postaddicts can distinguish heroin from morphine after intravenous injection (but not after subcutaneous injection). The basis for such successful discrimination is difficult to identify, except perhaps

for the much higher incidence of reports of pins and needles following intravenous injection of morphine.

The comparative effects of methadone and meperidine have not been investigated with such precision, but clinical experience indicates that the over-all effects of these agents are much the same as those of morphine, except for duration of action—methadone somewhat longer and meperidine shorter. Meperidine is also said to produce less pupillary constriction, presumably because of a peripheral anticholinergic action.

Opiate poisoning. The minimum human lethal dose of morphine is not known. Death has occurred after administration of 60 mg. of morphine, and, with vigorous treatment, recovery after intravenous injection of 760 mg. of morphine has been reported in nonaddicts. In the case of methadone, poisoning may occur after repeated injections of relatively small doses because of cumulative effects.

Regardless of the particular opioid involved, opiate poisoning is characterized by marked unresponsiveness, slow or periodic respiration, pinpoint pupils, bradycardia, hypotension, and hypothermia. In cases of very severe poisoning, the pupils may be dilated; reflexes (including the corneal) may be absent; cyanosis may be marked; and the pulse may be rapid, weak, and thready. In milder cases, opioid poisoning may be treated by vigorous and continued sensory stimulation and gastric lavage if the drug has been taken orally. In more severe cases, air passages should be cleared, an airway or trachea cannula inserted, and artificial respiration instituted.

If the patient does not respond promptly to these measures, one of the specific morphine antagonists, nalorphine or levallorphan, should be administered. Initially, a dose of 3 to 5 mg. of nalorphine may be given intravenously; if the diagnosis of opioid poisoning is correct, definite acceleration of respiration, return of blood pressure to normal levels, and reduction of miosis are invariably observed. Because the duration of nalorphine action is relatively short, the patient should be observed carefully, and additional doses of 5 mg of nalorphine should be given intravenously or intramuscularly as required until vital signs remain at acceptable levels. Restoration of consciousness is less promptly effected by the morphine antagonists and should not be a primary goal of treatment, since overdosage with morphine antagonists may develop if such is attempted. Great care must be exercised in administering morphine antagonists to physically dependent addicts who have taken an overdose of an opioid, since relatively small doses of an antagonist may precipitate violent abstinence phenomena.

Chronic intoxication. With repetition of a given dose of morphine, particularly two or more times daily, tolerance develops at varying rates, depending on the effect under consideration. Euphoria, relief of pain and anxiety (if previously present), depression of respiration, nausea, and vomiting decrease at a

relatively rapid rate. Pupillary constriction declines less rapidly, and smooth muscle spasm, with attendant constipation, persists indefinitely. Although the adrenal glands and the gonads remain responsive to appropriate hormonal stimulation, ACTH production is continuously depressed. In the sexual sphere, males become impotent, and females cease to menstruate.

Increasing the dose of morphine may partially restore the original effects of the drug, but addicts have been known to increase the daily dose to 5,000 mg. or more in an attempt to regain euphoria, with only partial and transitory success. Indeed, histories given by addicts and the results of a study by Wikler of a patient during experimental self-regulated readdiction to morphine indicate that, once a high degree of tolerance and physical dependence have been established, the prevailing mood of the addict is predominantly dysphoric, he is beset with anxiety and guilt feelings, and the chief motivation to continue use of the drug is suppression of abstinence phenomena.

Generally, addicts place a negative value on morphine abstinence phenomena and their suppression by morphine, but the experimental subject referred to above compared early abstinence phenomena with hunger and their suppression by the next dose of morphine with the pleasure of eating a good steak when hungry. According to Lindesmith, conscious recognition that his recurrent discomforts are due to morphine abstinence and that their relief can be accomplished only by an agent designated as morphine serves to identify the user as an addict in his own eyes and to initiate him into the value systems of other addicts.

Abstinence phenomena. The abstinence syndrome that develops when repeated injections of morphine are suddenly terminated is quite stereotyped. Although the patient may complain much earlier, frequent yawning, rhinorrhea, lacrimation, pupillary dilation, sweating, piloerection, and restlessness are usually observed 12 to 16 hours after the last dose. Later, muscular aches and twitches, abdominal cramps, vomiting, diarrhea, hypertension, insomnia, anorexia, agitation, profuse sweating, and weight loss develop, together with mild hyperglycemia and marked increase in urinary excretion of 17-hydroxycorticosteroids, indicative of greatly augmented pituitary ACTH production. In addition, spontaneous ejaculations may occur in the male and profuse menstrual bleeding in the female.

This constellation of signs, together with more variable behavior changes, reaches peak intensity on the 2nd or 3rd day after the last dose of morphine and then subsides rapidly over the next week, but, as already noted, a stable state may not be achieved for 6 months or longer. If, at any time during this abstinence period, a single dose of morphine is administered, all the abstinence phenomena subside dramatically, only to reappear again within 4 to 6

hours at a level comparable to that which would have been observed had morphine not been administered. The untreated morphine abstinence syndrome is rarely fatal except in patients with cardiac disease, active tuberculosis, or other debilitating illness.

In general, the abstinence syndromes following withdrawal of other opioids in patients addicted to them are similar to that of morphine. In the case of meperidine, however, myoclonic jerks or generalized convulsions, with paroxysmal activity in the electroencephalogram, may be observed prior to drug withdrawal if the daily dose level attained during chronic intoxication is over 2,000 mg. Such convulsive phenomena disappear within a few hours after the last dose of meperidine and are replaced by extreme restlessness, profuse sweating, and isolated muscle twitches—the characteristic features of the meperidine abstinence syndrome. If the patient now takes his accustomed dose of meperidine, the cycle of toxic convulsions and extreme abstinence restlessness, sweating, and muscle twitching may be repeated. In contrast, the abstinence syndrome that ensues when methadone is abruptly withdrawn from tolerant and physically dependent patients is much milder than that of morphine but persists longer, so that they are apt to complain of muscle and bone aching, irritability, poor appetite, and disturbed sleep for several weeks after withdrawal. Recent comparative studies by Martin and Fraser indicate that, contrary to earlier views, the morphine and heroin abstinence syndromes are quite comparable regarding time of onset, peak intensity, and rate of decline, provided that comparisons are made after stabilization of the patient at equipotent daily dose levels of the two drugs.

Much more rapidly developing abstinence syndromes can be precipitated in patients tolerant to and physically dependent on most opioids by injection of a morphine antagonist, such as nalorphine or levallorphan. Depending on the route of administration of the antagonist—subcutaneous, intramuscular, or intravenous—tachypnea, mydriasis, sweating, piloerection, rhinorrhea, lacrimation, and yawning characteristically appear within a few minutes. If the administered dose is relatively large, the entire morphine abstinence syndrome can be developed in violent form shortly thereafter. In the case of morphine, the precipitated abstinence syndrome begins to decline after about 45 minutes. During this time, it cannot be suppressed by injection of opioids; in fact, the precipitated abstinence syndrome may be intensified by these agents. The precipitated methadone abstinence syndrome is comparable both in time course and in intensity with that of morphine, contrasting with the lower intensity and more prolonged time course that characterizes the methadone withdrawal syndrome. In contrast, the morphine antagonists are far less effective in precipitating abstinence phenomena in patients tolerant to and physically de-

pendent on meperidine at stabilization dose levels of less than 3,000 mg. a day.

Diagnosis. Detection of needle marks and bluish phlebotic scars in the antecubital fossae or elsewhere on the body may indicate that the subject has used opioids from illegal sources in the past, and the presence of miosis and some degree of drowsiness should suggest that the subject is under the influence of opioids at the time of examination. If the subject has used opioids within the previous 24 hours, their presence in the urine can be demonstrated by chemical or chromatographic tests.

Physical dependence on opioids can be established only by demonstration of the typical abstinence syndrome. This may be accomplished simply by repeated observation of the patient over a period of 24 to 48 hours in a drug-controlled environment or more rapidly by administration of a morphine antagonist. Most commonly, *N*-allylnormorphine (nalorphine, Nalline) is used for this purpose. This drug should be given subcutaneously, and the first dose should not exceed 3 mg. If mydriasis, tachypnea, sweating, yawning, piloerection, lacrimation, and rhinorrhea are not displayed within 20 minutes after the first injection, a second dose of 5 mg. may be given. If such signs are not elicited within 20 minutes after the second injection, a third and final dose of 7 mg. may be given. If this dose also fails, the test is considered negative. The results of the Nalline test cannot be considered positive unless the pattern of precipitated abstinence signs is characteristic; mere dilation of the pupil, for example, may conceivably occur in an anxious but nonaddicted person who is receiving an injection to which he is not accustomed.

Natural History

In a study by Rayport on 1,500 consecutive admissions to the United States Public Health Service Hospital in Lexington, Kentucky, during a 4-month period in 1952, it was found that 29 per cent of white and 1.2 per cent of Negro patients stated that they first received narcotics from a physician, frequently enough to become addicted, in the course of treatment for painful illnesses. Such an onset of addiction is also commonly reported by physician addicts, but a large number of these patients state that they began to use opioids, most often meperidine, for reduction of fatigue under the stresses of medical practice. Most commonly, however, addicts ascribe their initial use of drugs to curiosity.

Typically, the initial phase of drug abuse begins in the late teens or early twenties and is characterized by experimentation with drugs of all sorts, including alcohol, amphetamine, cocaine, barbiturates, marijuana, and heroin and other opioids. For reasons that have not yet been clearly delineated, a number of such individuals find the opioids most rewarding and eventually use drugs of this class in preference to the

others. Cocaine is also highly valued, but, because of its propensity to produce alarming degrees of anxiety or hallucinatory states, users of cocaine usually combine this drug with heroin and claim that the combination ("speedball") enhances the effects of the heroin content. According to Chein et al., many users of opioids engage in the practice repeatedly but at highly irregular intervals, thereby avoiding the development of tolerance and physical dependence. Others, however, rapidly become both tolerant and physically dependent, and with these processes a new phase of drug abuse begins.

Under prevailing social conditions, the addict's life is now dominated by the pharmacologically engendered need for the drug, which can be acquired only through "hustling"—more or less frantic activity concerned with locating sources of supply, making the necessary contacts, evading the police, securing the necessary funds for purchase of the drug by illegal or legal means, changing residence frequently to avoid detection, etc. Successful hustling, however, is not without its rewards, since the successful "hustler" is highly esteemed by addict society. Failure of drug supply, arrests for violation of the narcotics laws or for criminal offenses, and pressures from family or friends often interrupt this way of life, but in most cases hustling for drugs is resumed shortly after "cure."

There is some evidence that the alternating sequence of cure and relapse is not interminable. Winick has called attention to the sharp increase in the rate at which names of addicts between 35 and 40 years of age are dropped from the list of active addicts of the Federal Bureau of Narcotics. According to Winick, the proportion of dropouts at each age is not the same as the proportion at each age in the current addict population, indicating that, for some reason, addiction is a self-limited illness—average length of addiction estimated at 8.6 years—for a large number of addicts. Conceivably the drop-off between 35 and 40 could be due to early death, prolonged incarceration in penal or mental institutions, or acquisition of more effective skills in evading the law, but the possibility remains that physical and psychological maturation may effect a cure of narcotic addiction without benefit of formal treatment. These divergent hypotheses remain to be resolved by further research.

Etiology

The interactions of sociological, personality, pharmacological, and conditioning factors in various phases of the habituation process are summarized in Table I.

Sociocultural factors. As already noted, the majority of present day addicts in the United States are derived from the most depressed slum areas of the large metropolitan centers, in which illicit sources of drug supplies are more available than elsewhere and

TABLE I
Dynamics of Drug Abuse: Instrumental Conditioning Paradigm^a

Phase	Discriminative Stimuli	Reinforcement Processes				Behavioral Phenomena	Drug Effects
		Schedules	Sources				
			Primary	Secondary	Auxiliary		
I. Episodic intoxication (euphoria)	More frequently, bad associates; less frequently, medical contingencies	Occasional	Anxieties (homeostatic, sexual); curiosity; boredom; anhedonia	Anomie; hostility	Effort factor	Experimenting with drugs	Objectively unwarranted sense of "unusual well-being"; indifference; elation
II. Pharmacogenic dependence (addiction)	Bad associates	Continuous or aperiodic	Mainly homeostatic and sexual anxieties induced by cellular counter-adaptations to repeated doses of addicting drugs	Status in addict society	Effort factor (intensified)	Progressive increase in dosage (tolerance); "hustling" for drugs	Gratification of craving
III. Relapse after cure (habituation)							
Early	Medical and law enforcement contingencies	Extinction by satiation (not nonreinforcement)	Same as in phase II, but decreasing after peak	Hostility; guilt	Generalization of anxiety	Abstinence syndrome	Relief of abstinence distress
Late	Bad associates; sensorial effects of drugs	Variable	Conditioned sources of reinforcement, generated mainly in phases II and III (early)			Conditioned abstinence phenomena (fragmentary)	As in phase I plus drive (conditioned hustling?)

^a Adapted from Wikler, A. On the nature of addiction and habituation. *Brit. J. Addict.*, 57: 77, 1961.

in which prevalent attitudes toward the law and standards of behavior are more psychopathic than in more economically favored areas. Sociologists have found little evidence that systematic recruitment of young persons into the population of addicts by "pushers" plays a significant role in the genesis of drug addiction. Rather, most addicts blame "bad associates" for their introduction to drug use, meaning thereby that they were impelled to experiment with drugs through identification with others who were already addicts.

The importance of availability of opioids is illustrated by the relatively high incidence of addiction among physicians and related professionals, who constituted 1.8 per cent of all admissions to the United States Public Health Service Hospital in Lexington,

Kentucky, in 1955. It is estimated that 1 or 2 per cent of 1st year medical students will become addicted to opioids at some time in their medical careers.

Personality factors. As in the cases of other conditions they purport to explain, psychoanalytical writings, such as those by Fenichel, on drug addiction have described the behavior of opioid addicts in terms of regression and fixations at pregenital, oral, or even more "archaic" levels of psychosexual development. More operationally, postaddicts at the United States Public Health Service Hospital, Lexington, Kentucky, have been found to yield Minnesota Multiphasic Personality Inventory (MMPI) profiles that are characterized by significant elevations on the Pd (psychopathic deviate) and Ma (hypomanic) scales, with lesser elevations on the Sc (schizophrenic) and D

(depression) scales. These profiles, however, do not differentiate postaddicts from institutionalized alcoholic patients and juvenile delinquents without alcoholism or narcotic drug addiction.

In more conventional though less precise descriptive clinical terms, other investigators have stressed passive dependency as a dominant trait among opioid addicts. Wikler and Rasor have suggested that such individuals prefer opioids to alcohol and other drugs because the opioids facilitate their preferred mode of dealing with stressful conditions, namely, by promoting indifference and withdrawal. Gerard and Kornetsky compared the personalities of institutionalized young opioid addicts with those of nonaddict acquaintances living in the same slum area in New York. Although these investigators found what they considered to be a higher incidence of incipient or overt schizophrenia among the addicts, the control subjects were far from normal by conventional standards. This finding emphasizes a point made by Clausen, namely, that conventional concepts of normality and abnormality in relation to personality characteristics may not apply, at least without considerable qualification, to the population from which the majority of addicts are drawn. Studies on the personality traits of nonaddict siblings of addicts may be of value in determining whether or not there are actual differences, but the causal relationship of such differences to the genesis of opioid addiction can be elucidated only by longitudinal prospective studies on a large sample of the population in areas with high narcotic addiction rates.

Pharmacological factors. Wikler and Rasor have emphasized the specificity of choice of drugs for repeated use by those who eventually become habitual opioid addicts, and these authors have attempted to relate such specificity to the demonstrable specificities in the pharmacological actions of the opioids.

From a psychodynamic standpoint, the most relevant actions of single doses of opioids lie in their capacity to reduce drives generated by *primary* needs—relief of pain and other physical discomfort, reduction of sexual urges and of hunger, the first two being of greatest importance in our society, contrasting with the action of alcohol and barbiturates, which do not reduce such drives but reduce inhibitory control of behavior directed toward satisfying needs directly.

In this writer's view, the genesis of physical dependence by repeated injections of opioids provides a new *organic need* that is drive-inducing, the reduction of which is positively reinforcing (pleasurable). Furthermore, such drive induction provides the addict with a motive for sustained activity directed to a goal, namely, the acquisition and self-administration of opioids in an ever recurring, cyclic manner—an asset that presumably was lacking prior to addiction. In this view, physical dependence-producing drugs (such as the opioids, barbiturates, and alcohol) are

capable of producing sources of reinforcement that add to those already present in the personality structure of the future addict, a property not shared by drugs (such as cocaine, marihuana, amphetamine) that do not produce physical dependence.

Conditioning factors. Emphasizing the central role of physical dependence, both in perpetuating continued use of opioid drugs and in relapse, Wikler postulated that abstinence phenomena may become conditioned in the classical Pavlovian manner to environmental contingencies that are temporally contiguous with the occurrence of such abstinence phenomena. Occasionally, addicts report that long after cure they experience discomforts that can be interpreted as conditioned abstinence phenomena when they return to the environment in which they had previously become addicted and frequently were acutely abstinent.

Experimentally, Wikler has demonstrated classical conditioning of a morphine abstinence sign in the rat. Also, as has already been noted, cyclic occurrence of abstinence phenomena and their relief by the next dose of the drug during periods of maintained morphine addiction should, at least theoretically, lead to reinforcement of drug-seeking behavior. This has been demonstrated experimentally in animals by several investigators. It has also been reported that, when so reinforced, drug-seeking behavior in rats persists after withdrawal of morphine. In other studies, however, it has been shown that, following withdrawal of morphine after a period of addiction, the physiological state of rats continues to deviate from normal for 6 months or more and that postaddict rats that have not had reinforcement training during addiction also consume significantly larger quantities of an opioid drug than nonaddicted control rats.

Tentatively, at least, it must therefore be concluded that, regardless of the roles played by classical conditioning of abstinence phenomena and operant conditioning of drug-seeking behavior during maintained periods of addiction, previous physical dependence per se plays a very important role in the genesis of subsequent relapse.

Treatment

Although the practicability and the long term consequences of maintenance therapy are currently being investigated experimentally in some research centers, notably by Dole and Nyswander, the generally accepted aims of treatment are drug withdrawal and rehabilitation of the patient, with the end in view of enabling him to lead a useful and reasonably satisfying life without medically unwarranted use of drugs.

Drug withdrawal. To achieve the goals of this phase of treatment, confinement in a drug-controlled institution is always desirable and in most cases essential. Immediately after admission, a complete medical and psychiatric history should be taken, and

a careful physical examination should be made. In particular, the history should contain a detailed account of all drugs taken by the patient, including dosage, frequency, and route of administration. It is especially important to ascertain if and to what extent the patient has been taking barbiturates and nonbarbiturate sedatives in addition to opioids, since severe barbiturate-type withdrawal phenomena (convulsions, delirium, hyperthermia) may terminate fatally. For maximal safety, chromatographic analysis of a urine sample for these drugs should be made routinely if facilities are available, regardless of whether or not the patient admits use of drugs of this type. The concomitant use of cocaine, drugs of the amphetamine series, or marihuana presents no special problem in management, since abrupt withdrawal of these agents is not followed by an abstinence syndrome. Opioid addicts rarely use alcohol concomitantly, but if such usage has been the case, the treatment program of choice is that described below for combined opioid and barbiturate addiction. Regardless of the drug history obtained, a careful search should be made of all body orifices, clothing, and accessories for concealed drugs.

If opioids alone have been used by the patient, two methods of withdrawal have proved equally successful: rapid reduction and methadone substitution.

Rapid reduction. Initially, the patient is stabilized for 2 or 3 days on a dose and frequency of subcutaneous injection of morphine just sufficient to prevent the appearance of opioid abstinence phenomena. Generally, morphine can substitute adequately for any opioid, although in the case of meperidine, some difficulties may be encountered. The size of the dose and the frequency of injection varies with the amount and nature of the drug to which the patient has become addicted, but it is rarely found necessary to administer more than 30 mg. of morphine subcutaneously every 6 hours. Because addicts tend to exaggerate the amount of drug they had been using, overdosing with morphine may occur, and treatment for opioid poisoning may have to be instituted, as described above.

After the initial stabilization period, withdrawal by rapid reduction may be accomplished over a period of 5 to 10 days, depending on the general health of the patient and the severity of such withdrawal phenomena as may occur. Reduction may be made on a dose-to-dose basis or on successive days, keeping the four daily injections at the same dose level. When the dose schedule has been reduced to 10 mg. of morphine four times daily, 30 mg. of codeine may be administered, together with smaller amounts of morphine, for 1 day, and codeine alone may be administered in decreasing amounts for an initial day or two.

General supportive therapy, including intravenous infusions of 5 per cent glucose in saline, warm continuous flow baths, aspirin for aches and pains, and small doses of barbiturates for sleep should be pre-

scribed when indicated. If the patient is well nourished and his dietary intake is adequate, vitamins are unnecessary, but they should be administered if deficiency exists.

After the initial 5- to 10-day period, one or two small "pick up" injections of morphine (6 to 10 mg.) may be given if the rapid reduction procedure has been attended with considerable physical discomfort. However, such pick ups must not be continued indefinitely. The time schedule for rapid reduction may be extended in cases of active pulmonary tuberculosis or cardiac insufficiency or other debilitating disease, according to the judgment of the physician.

Methadone substitution. Initially, the patient is stabilized on a dose of methadone in flavored aqueous solution given twice daily by the oral route, the dose just sufficient to suppress opioid withdrawal phenomena. For this purpose 1 mg. of methadone can be considered equal in abstinence-suppressing potency to 3 or 4 mg. of morphine or 1 mg. of heroin or 0.5 mg. of hydromorphone. If uncertainty as to the accustomed dosage of opioid exists, a first trial dose of 10 mg. of methadone and subsequent doses adjusted in accordance with the patient's response may be given. In most cases 10 to 20 mg. of methadone twice daily by the oral route suffices.

After stabilization of methadone is accomplished, this drug may be withdrawn by progressive reduction of the dose over a period of 3 to 10 days. When properly carried out, withdrawal by methadone substitution is attended by only minimal signs of autonomic disturbance, but, beginning 3 or 4 days after the last dose of methadone, the patient may complain of vague aches and pains, weakness, loss of appetite, and disturbed sleep for several weeks. As in the case of withdrawal by rapid reduction of morphine, supplementary therapy may be required.

As already mentioned, withdrawal of meperidine may present some difficulties. This is because smooth substitution of morphine or methadone without excessive sedation is difficult to accomplish, especially when the patient has been addicted to dose levels of meperidine that produce toxic convulsive phenomena. In such cases, the patient may be stabilized on meperidine itself by reducing the total daily dose to levels that do not produce convulsive phenomena, at the same time increasing the frequency of injection to every 2 to 3 hours in order to prevent reappearance of meperidine abstinence phenomena. After successful stabilization has been accomplished for 2 to 3 days, meperidine can be withdrawn by rapid reduction in the manner employed for withdrawal of morphine by this method.

Special problems also occur in the management of patients addicted to both opioids and barbiturate-type drugs. In such cases, the patient is first stabilized both on barbiturates and on morphine or methadone. Stabilization on barbiturates is accomplished by administering pentobarbital orally in doses that are

just sufficient to produce a mild degree of intoxication as manifested by the presence of nystagmus, mild ataxia, and perhaps some slight slurring of speech. Stabilization on morphine or methadone is accomplished in the manner already described. The stabilization dose schedule of pentobarbital is then continued without change, and methadone or morphine is withdrawn by rapid reduction; only thereafter is withdrawal of pentobarbital undertaken. This is accomplished by very gradual reduction of the dose of pentobarbital at a rate not exceeding 100 mg. a day. Should even minor barbiturate abstinence phenomena develop—such as tremulousness, sweating, insomnia, anorexia, postural hypotension—further reduction is suspended until these signs have disappeared, after which the pentobarbital reduction schedule is resumed at the same rate. Depending on the dose level and duration of addiction to barbiturates or non-barbiturate sedative drugs, withdrawal of these agents may take a month or even longer.

Rehabilitation. Because of evidence already cited indicating that opioid abstinence deviations persist for 6 months or longer after drug withdrawal, continued residence for at least several months in a drug-controlled institution is deemed essential. During this time, physical defects, if present, can be corrected and occupational therapy provided in anticipation of the patient's eventual return to normal society. Many patients are amenable to group psychotherapy and a smaller number to individual psychotherapy. During this time, also, plans should be worked out for follow-up counseling, employment, and, if possible, change of residence for the patient if his previous home environment has been one that would be conducive to renewed contacts with addicts and sources of drug supply. After discharge from the institution, some patients may benefit from association with groups such as Addicts Anonymous or Synanon.

Results. It is generally agreed that the short term results of treatment of opioid addicts are very discouraging. In a follow-up study by Hunt and Odoroff on a large group of addicts returning to New York after treatment at the United States Public Health Service Hospital in Lexington, Kentucky, it was found that "more than 90 per cent of the patients followed became readdicted and did so within six months after discharge from the hospital."

However, substantially better results have been observed by O'Donnell in a group of 266 opioid addicts discharged from the United States Public Health Service Hospital in Lexington, Kentucky, who were residents of rural areas in that state. Of this group, 144 had died, but of the surviving 122, 50 had abstained from drugs completely for periods of 2 to 18 years.

The prognosis also seems to be better in the case of physician addicts, provided they are placed on probation for a number of years after treatment and are

required to report to a supervisory board for the purpose of presenting evidence of continuing abstinence from medically unwarranted drug use. In California, where this procedure has been in effect since 1948, the incidence of successful completion of the probationary period and restoration to medical practice has been very high—92 per cent for the years 1948 to 1952.

Explanations for the generally disappointing results of treatment of opioid addicts usually emphasize the acknowledged difficulties inherent in attempts to alter basic personality characteristics. This may be conceded, but theoretically, at least, it should be possible to reduce or eliminate the roles played by conditioning factors in the genesis of relapse. For this, some method of extinguishing conditioned abstinence phenomena and the reinforcement of drug-seeking behavior by the rewarding effects of the drug itself will have to be devised.

In this connection, a proposal has recently been made by Martin et al. based on the experimental finding that stabilization of postaddicts on relatively small doses of the powerful morphine antagonist cyclazocine renders them highly resistant to the euphoric as well as the physiological effects of morphine and heroin, even when these drugs are administered in doses far greater than those that the average addict is likely to obtain on his own initiative. Furthermore, postaddicts continuously maintained at a stabilization dose level of cyclazocine (2 mg. per 70 kg. body weight twice daily by mouth) do not develop a significant degree of physical dependence on morphine, even when the latter is given subcutaneously four times daily in amounts and over a period that would definitely produce physical dependence if cyclazocine has not been administered concomitantly. Thus, a postaddict stabilized on cyclazocine would not experience euphoria should he administer morphine or heroin to himself after discharge from the hospital, nor would he develop physical dependence on these opioids if he engaged in this practice repeatedly. If conditioned abstinence should occur when the postaddict returns to his drug-significant environment, he would not be able to relieve the discomforts associated with such phenomena by self-administration of opioids. According to conditioning theory, the "immunization" provided by cyclazocine should, therefore, promote extinction of drug-seeking behavior by eliminating its rewarding properties. The impact of such a form of treatment on the over-all problem of opioid addiction depends on the degree to which postaddicts will voluntarily cooperate in the program, but there is no reason to doubt that at least some patients would do so. The results of further research with this method of immunization will be eagerly awaited.

27.2 ADDICTIONS. II: NON-NARCOTIC ADDICTIVE AGENTS

JOHN A. EWING, M.D.

The various problems in defining drug addiction and habituation have been discussed in the previous section. In this section the term "drug dependence" is interchangeable with what the layman calls "addiction."

All the drug dependencies represent a group of illnesses with many features in common. These are not just chemical diseases but involve a complex interaction of physiological, pharmacological, personality, and socioenvironmental factors.

History

Alcohol and narcotics have been used for their psychic effects for thousands of years. Man has also used other substances in a hedonistic way, for example, tobacco, betel, Indian hemp, and some of the hallucinogenic drugs. But it is only in comparatively recent times that a large variety of non-narcotic, non-alcoholic drugs of potential dependence has been available. Bromides began to be used in medicine about 1830 and were introduced in the treatment of epilepsy in 1857. Thereafter, the complication of excessive sedation by bromides began to be observed. In 1930, Diethelm reported that 40 per cent of patients admitted to the psychiatric wards of The Johns Hopkins Hospital could be shown by laboratory tests to have

taken some bromide, and 2 per cent had toxic symptoms.

Barbiturates were introduced in 1903, and as recently as 1938 some physicians claimed that there was no resulting physical dependence. Yet the literature contained reports that barbiturate addicts could develop convulsions or psychoses when deprived of their drug.

A similar history could be listed for many of the nonbarbiturate sedative drugs. Most of the newer substances to be listed below have been introduced as non-dependence-provoking or non-habit-forming. Although this is true at the ordinary recommended dose, it seems clear that there will always be some people who will keep increasing the dose as tolerance develops.

Epidemiology

The occurrence and distribution of this condition are not known. Probably the incidence of dependence on drugs is higher now than at any previous time in history, reflecting availability of drugs, social attitudes about drugs and tranquilizers, cultural tendencies to regard tension as abnormal and freedom from anxiety as desirable, and problems of a psychological nature in the individuals involved.

Physicians. The tendency for members of the health professions to become addicted to narcotics is well recognized. Less well known is the high incidence of dependence on drugs other than narcotics. The availability of such medications is only part of the reason. In addition, the psychological makeup of those who enter the medical and allied professions must be taken into account. It is unwise to overgeneralize, but at least it is reasonable to note the tendency for many such people to avoid the role of patient whenever possible. Many physicians who are treated for addiction to drugs show strong reaction formations to intense dependent drives. Such people prefer to avoid seeking help. When illness forces them to do so, they tend to accept this state of affairs very reluctantly. This results in a preference of some physicians for self-medication rather than help from others. Thus begins a vicious cycle: under conditions of fatigue, anxiety, pain, or even disappointment, the physician turns to something he can swallow. By thus relieving his symptoms, he avoids, for the time being, a more overt expression of oral regression.

A good rule for a physician to live by is never to medicate himself, whether with tranquilizers, barbiturates, or something stronger. If medication is necessary, its being prescribed by and controlled by a colleague will largely circumvent the danger of becoming drug-dependent.

Patients. Lewin has pointed out that the medical student's first patient is a cadaver. "Intended to be a prototype of all future patients in certain rational respects, the cadaver easily comes to be the student's ideal of a patient in all respects." Lewin goes on to

state that doctors know unconsciously that sick people are aggressive, either to the environment or to themselves. Counter-aggression on the part of the doctor has to be sublimated. For example, the doctor uses medications that can be poisonous in excessive amounts. Likewise, he can overtranquilize his patient. It is important, therefore, to keep in mind that excessive medication can be contributed to by the physician. It may be the end result of counter-transference reactions within him.

Characteristics

The development of tolerance to and dependence on the addicting substance are important characteristics of addiction, as is the phenomenon of withdrawal reaction, which occurs when a drug to which an individual is addicted is discontinued.

The withdrawal or abstinence syndrome shows a particular group of features characteristic of the drug involved, including psychic and physiological types of response. The abstinence syndrome can be relieved by administration of the drug itself or by another one of similar pharmacological activity. The condition is really an acute brain syndrome associated with drug withdrawal. The American Psychiatric Association classification does not at present provide for this, although it does recognize brain syndromes associated with drug intoxication.

Many drugs capable of inducing dependence produce psychotoxic effects as well, especially in higher dosages or in chronic administration. This is particularly true of alcohol and the drugs to be discussed here, in contrast to narcotics, where addicts may show little change other than marked reduction of aggressive and primary biological drives.

Barbiturates

The barbiturates are probably the most significant group of substances involved in drug dependence other than narcotics and alcohol. They also represent a typical group of central nervous system depressants. Much of what can be said about barbiturates could be repeated about other sedative drugs.

Etiology. Although barbiturate dependence has undoubtedly existed for over 50 years, its recognition has mainly come in the last 25. It is certain that barbiturates and other drugs do reach dependent persons by illegal routes, but it is also clear that physicians contribute to this problem by carelessness, by lack of vigilance or knowledge, and sometimes perhaps by a psychological counter-transference reaction to the patient. The barbiturates can be a useful symptomatic treatment, but prolonged reliance on them for the suppression of symptoms in the absence of a fuller diagnosis is completely unjustified. Likewise, willingness to write repeated prescriptions or the failure to limit the number of times that a prescription can be refilled may be a major error on the physician's part.

Personality factors. Characteristics that suggest

vulnerability for the development of dependence on barbiturates are greatest in patients with a history of dependence on other substances, including alcohol. The use of barbiturates for the treatment of alcoholics is unjustified; in fact, they do not really constitute a treatment. They are occasionally useful in the management of alcohol withdrawal, but better drugs, such as chlorthalidazine, are available.

Can a person without underlying psychopathology become dependent upon barbiturate drugs? Clinical experience suggests that dependence occurs only in the emotionally maladjusted person. These people are seeking relief of unbearable feelings of tension and anxiety. The drug becomes an escape route in preference to finding more personal forms of adaptation. Typical sources of mental anguish for such people can be intrapsychic conflicts over aggressive, sexual, and dependent wishes; feelings of inadequacy and of being overwhelmed; and the symptoms of specific psychiatric syndromes.

Often the patient can be characterized as a passive-aggressive personality, passive-dependent type. A history of a weak or absent father and an indulgent but rejecting mother is common. A tendency to be manipulative of others is often observed as the patient seeks gratification from the environment.

Although dependency on barbiturates is a fairly specific process, all types of psychiatric disorganization may be found underlying it. Thus, it is important to give the patient careful individual study and a specific therapeutic program, in the absence of which the potential for repeated relapses is very considerable.

Characteristics. Barbiturates, like alcohol, have a disinhibiting effect. This may give rise to release phenomena, such as the expression of aggression or dependent wishes that might, under sober circumstances, provoke too much guilt to be carried out.

When there is much behavioral change during intoxication, the physician should study this carefully. For example, the occurrence of belligerence during intoxication and not at other times points to the existence of conflicts about the expression of aggression. Taking a history from a family member can often help by revealing the existence of such behavioral changes.

Some patients begin with barbiturates, usually the short-acting ones, for anxiety or insomnia and gradually increase the dosage. Others try to balance barbiturates against stimulating drugs, such as amphetamines, with gradual increase of dosage a frequent result.

A daily dosage of seven or eight capsules or more, each capsule 100 mg., cannot be discontinued suddenly without great discomfort and possibly dangerous complications. Isbell (1950) found that subjects taking 800 mg. or more daily of pentobarbital or secobarbital developed weakness, tremor, and anxiety in all cases after withdrawal; 75 per cent showed convulsions; and 60 per cent showed a picture similar to delirium tremens. Those taking 600 mg. daily developed anxiety,

tremor, and weakness; those taking less than 400 mg. daily had only minor symptoms. Thus, physical dependence occurs in cases of abuse and not within the usual dosage range.

Diagnosis. This has to be based on the patient's mental confusion, intellectual impairment, personality changes, and motor incoordination. Some patients become aggressive, but many simply show dullness and excessive drowsiness. Electroencephalograms may show increased β waves of 15 to 30 cycles per second.

One cannot depend entirely on diagnosing intoxication from sedation and lethargy, which often disappear after a few days following any increase in dosage. More important is a thoroughly detailed neurological evaluation and a careful administration of a mental status examination. Only in the most extreme instances will disorientation be found; however, slight but distinct impairment may be detectable in almost all other areas of mental functioning and may supply the necessary clue to suggest the diagnosis of drug intoxication.

Virtually all patients show extreme reluctance to reveal the nature of their symptoms. Typically, they understate the amount being taken, and no effort should be spared to obtain details from their family or drug store in order to determine the correct daily intake. Certainly the patient should be hospitalized for withdrawal, and an attempt should be made to explain to him the importance of knowing his daily intake in order to stabilize him at this level before withdrawing slowly and safely. Unfortunately, many of these people are suspicious and confused, and so cooperation cannot be counted upon.

In a general hospital, some cases first reveal themselves by apparent acute anxiety symptoms, delirium tremens, or the occurrence of a convulsion. Underlying a barbiturate coma may be a barbiturate dependence. Sometimes as a result of accidental or intentional overdosage, the patient may be hospitalized, with all drugs being stopped. Then, around the 2nd or 3rd day, the withdrawal syndrome fully appears.

The syndrome resulting from abstinence must be recognized for what it is in order to institute effective treatment. If untreated, the condition usually lasts for at least 4 or 5 days and involves much delirium, with insomnia, confusion, tremors, hallucinations, delusions very much as in delirium tremens of alcoholism, and, sometimes, convulsions. Clinical improvement is usually seen after a prolonged period of sleep. The entire condition is dangerous but leaves no apparent residua after recovery.

The earliest sign of the abstinence syndrome is insomnia accompanied by complaints of weakness, restlessness, sweating, and shakiness. The patient may feel generally anxious and apprehensive. Some postural hypotension is likely to appear, along with muscular twitching, vomiting, increased anxiety, some fever, psychotic behavior with hallucinations, delirium, and great fear, as in delirium tremens. Convulsions usually appear 15 or more hours after with-

drawal, with the peak at 30 hours, and some seizures appearing as late as the 4th or 5th day. Psychotic symptoms typically begin later than convulsive ones, between the 3rd and 7th days.

Management. As a simple rule of thumb, a daily reduction of the total dosage by no more than 10 per cent of the established daily intake is recommended. Even this rate of withdrawal may be excessively rapid for the patient who has been taking 20 or more capsules daily. At least to begin with, he should be withdrawn at the rate of about one capsule less per day.

The ideal management of the barbiturate withdrawal is begun by knowing the patient's daily intake from the beginning and stabilizing him on this amount for at least the first day or two. On this amount he may show a mild degree of intoxication and sedation. If he begins to show abstinence signs or symptoms, the dosage is too low, usually because he understated his normal amount. If he appears excessively sedated, he has overstated it, and some downward adjustment is called for.

When the patient will not or cannot state his total normal daily dosage, a test dose is called for. This is not given to a patient who is obviously intoxicated, and it may be insufficient for the patient who is already showing the abstinence syndrome. The latter probably requires more than the test dose.

The test dose suggested is 200 mg. of pentobarbital by mouth on an empty stomach. This is not an excessive amount for a patient who has any tolerance to barbiturates, provided he is not currently showing considerable sedation. Half that amount may be used for debilitated or elderly patients initially. The patient is evaluated 1 hour later. If the abstinence syndrome is still in evidence, the same dose should be repeated at once. After 1 hour, if the patient has no tolerance to pentobarbital, he will be soundly asleep but able to be aroused. If he is awake but somnolent and showing nystagmus, some difficulty in focusing his eyes, slurred speech, Rombergism, and considerable ataxia, he is probably able to tolerate only 500 or 600 mg. daily. If he shows only lateral nystagmus without ataxia, Rombergism, or somnolence, he is tolerant to about 800 mg. daily. If he shows no intoxication 1 hour after receiving 200 mg., he is tolerant to 10 or 12 capsules daily at least.

With a patient who admits to taking a daily dose of 12 or more capsules, each capsule 100 mg., an initial test dose of 300 mg. is quite suitable. Then, if he shows no intoxication, he is tolerant to at least 16 capsules a day. Mild signs of intoxication suggest a tolerance of 1,200 to 1,400 mg., and more severe signs of intoxication suggest that his daily tolerance is 1,000 to 1,200 mg.

The results of this study enable initial prescription of barbiturates for the management of the case. For patients requiring a total of less than 12 capsules daily, an administration schedule of four times a day

is adequate. Those taking a total daily dosage above this may require medication every 4 hours.

An attempt must be made to get the patient to a state of mild intoxication. Frequent observations should be made to enable a flexible schedule to be followed. For example, if severe intoxication is observed, the next dose of pentobarbital should be reduced by at least 100 mg. Likewise, if some of the physical signs of withdrawal are apparent, rather than just the patient's professed anxiety and apprehension, the next dose may have to be increased by the same amount.

Once the patient's tolerance level has been established and he is clearly in a state of comfort, the plan must be to withdraw the drug at the rate of no more than 10 per cent of the total dosage per day. A few patients, such as those showing an epileptic diathesis or severe debilitation, may have to be reduced at an even slower rate. The bedtime dosage should be maintained longest.

A potential complication with all such patients results from their having secreted private supplies of medication on their persons or among their property at the time of admission. If the clinical picture seems to vary inexplicably and not in relation to the dosage being given, the patient's possessions and room should be searched again. Another possibility always exists, namely, that family members or friends are bringing in additional supplies. Restricted visiting may be necessary.

Convulsive seizures will not occur on the schedule outlined above, except possibly in epileptic patients. If a convulsion does occur, the patient should be rapidly intoxicated by giving him 100 or 200 mg. of pentobarbital by mouth or intramuscularly every hour. Once his tolerance level has been reestablished, reduction should proceed again at a slower rate.

There is no substitute medication, as there is with narcotics addiction, on which barbiturate-dependent patients can be placed and then withdrawn. On the regimen outlined above, the need for additional medication, such as phenothiazines, does not occur.

All patients require general supportive measures, restoration of electrolyte balance, proper hydration with intravenous fluids, administration of vitamins, and a good balanced diet. Nurses should be aware of the potential of convulsive seizures in such patients. When these have occurred, either recently or in previous episodes, they should be especially wary.

The patient must be told, before discharge, of the possibility of some insomnia and irritability for several weeks or longer. He must know that he cannot ever again rely on hypnotics to induce sleep or allay anxiety. Now is the time to discuss psychotherapeutic help, with which he may acquire better ways of adapting to stress. The need for a continued long term relationship with family doctor, psychiatrist, or mental health center should be emphasized.

Meprobamate

History. The history of meprobamate (Miltown, Equanil) parallels that of the barbiturates. This drug was introduced into clinical practice around 1954, and reports of meprobamate dependence were published within 3 years. Next appeared reports of a withdrawal syndrome, including convulsions, in experimental studies in animals and in humans. The similarity to the barbiturates was then emphasized, and the importance of prescription with precaution was publicized. All this followed original publicity which stated that physical dependence and severe withdrawal symptoms did not occur. Since the early reports, the literature has repeatedly carried confirmatory case histories.

Characteristics. Toxic effects during the early stages of heavy meprobamate administration include somnolence, ataxia, some Rombergism, and systolic blood pressure drop, accompanied sometimes by complaints of dizziness and nausea. Patients rapidly adapt to the drug, and tolerance develops. Moreover, in the average ambulant patient, the dosage is usually increased at a sufficiently slow rate for such symptoms to be absent. Diagnosis of overdosage at this point is dependent on the patient's history, but the physician's suspicions may be aroused by observing some of the signs of central nervous system depressant effects, as in chronic barbiturate intoxication.

Withdrawal difficulties are rarely seen in patients taking less than six 400-mg. tablets daily and are essentially absent in patients taking only three or four tablets daily. However, the drug dependence-prone individual is just as liable to increase his intake of meprobamate as that of barbiturates.

Some withdrawal reaction will occur in 90 per cent of people taking 8 or more tablets daily if the drug is withdrawn suddenly. However, in about 75 per cent of the cases, the abstinence reaction is relatively mild, involving only insomnia, tremor, muscle twitching, anxiety, weakness, and nausea. When patients have been taking as much as 16 tablets daily, 95 per cent have withdrawal reactions. In more than half of these, the withdrawal reaction is fairly severe, involving more extreme signs and symptoms as listed above, plus convulsions in some instances and a full delirium picture similar to that following barbiturate withdrawal.

Management. Convulsions may be controlled by intravenous administration of diphenylhydantoin sodium. However, the over-all management of meprobamate dependence is best accomplished in a hospital, following a regimen similar to that used for barbiturates.

There is cross-tolerance for many of the central nervous system-depressant drugs and barbiturates. Most physicians, therefore, prefer to substitute a short-acting barbiturate, such as pentobarbital, and withdraw this. Equally good results can be obtained by reintoxicating the patient with the original medica-

tion and then withdrawing it. Again, the 10 per cent rule—that is, reduction over at least 10 days—is a useful one. Patients who have been taking only slightly excessive amounts may be withdrawn on an out-patient basis without undue discomfort if careful supervision is offered along with support.

Chlordiazepoxide (Librium)

Patients have become intoxicated and shown mental confusion on doses in excess of 80 mg. daily. One controlled study of chlordiazepoxide in 36 hospitalized patients showed the development of physical dependence. Following abrupt withdrawal from large amounts (300 mg. or more), an abstinence syndrome was seen. This involved insomnia, anorexia, agitation, nausea, twitching, sweating, and convulsions. Convulsions tend to occur considerably later than those following withdrawal of barbiturates or meprobamate. The management is similar to that described for meprobamate.

Paraldehyde

Dependence on paraldehyde is usually found among those with previous or concurrent dependence on alcohol or barbiturates. Occasionally, patients taking it for insomnia increase the dosage as they develop tolerance.

The diagnosis is based on the patient's history, the characteristic odor, the considerable disorganization to be detected on mental status examination, and the drowsiness or stupor of the patient. After withdrawal, a typical delirium picture is seen, as in the case of barbiturate withdrawal, and the condition is best treated in a hospital by reintoxication and then gradual reduction of the dosage. Again, reduction over at least 10 days is a good rule to follow for the average case of addiction to paraldehyde.

Other Depressant Substances

At present, these include chloral hydrate, ethchlorvynol (Placidyl), glutethimide (Doriden), methypylon (Noludar), methaqualone (Revonal), diazepam (Valium), dextropropoxyphene (Darvon), and ethinamate (Valmid).

A good review of addiction to various nonbarbiturate, sedative, and tranquilizing drugs is that by Essig, who pointed out that the abstinence syndrome includes convulsions and psychotic behavior and requires hospitalization. The treatment is gradual reduction of the drug in question or prior substitution with barbiturates. Anticonvulsants or phenothiazines alone are not enough for this condition. Indeed, the latter are contraindicated, as they may increase the likelihood of seizures and induce more hypotension.

Some patients take a slight overdosage of many different depressant drugs. The effect is similar to gross abuse of any one drug, but the diagnosis can be more difficult. The patient may swear that he just takes three "yellow jackets" (Nembutal) a day. Only persistent inquiry may reveal that he also consumes

several other pills and capsules of other hues. The correct treatment for such mixed addictions is to substitute pentobarbital to the point of mild intoxication, followed by gradual withdrawal as already described.

It is important to remember the sedative effect of many antihistamines, which are sometimes used in excess by drug dependence-prone patients, who abuse them for the sedative effect.

Phenacetin has been found to be associated with renal papillary necrosis. Its excessive use is found especially among those also indulging excessively in alcohol and other drugs.

Chronic excessive intake of aspirin is probably more common than is recognized. Neurological and psychiatric symptoms—agitation, confusion, memory loss, stupor, coma, paranoid ideation, and hallucinations—have been described in patients suffering from chronic salicylate intoxication.

Although there is no abstinence syndrome from bromides—perhaps because of the long period of time required for elimination of the drug, so that there is an automatic slow withdrawal—the possibility of toxic symptoms due to excessive intake of bromides is still present in some parts of the United States. Bromide-containing medicines are still available without prescription, and the existence of bromide intoxication may be missed in psychiatric hospitals' new admissions unless routine blood bromide testing is performed. Ewing and Grant recently found evidence of considerable self-medication with bromides in one Southern state.

Glue Sniffing

This subject has received considerable publicity in recent years throughout the lay press. Possibly in consequence, it has spread among teen-agers in widely separate parts of the country. Initially, it appeared in Denver, Colorado, where children were found seeking intoxication or even coma.

Characteristics. It is said that in the early stages a few whiffs of the vapor will produce a "jag." However, tolerance develops, and chronic users may have to take the contents of up to five tubes in order to experience the desired results of exhilaration, euphoria, and excitement, which are followed by ataxia and slurred speech. The phase of intoxication lasts from 30 to 45 minutes after inhalation, and drowsiness, stupor, and unconsciousness may ensue. Amnesia can occur for actions during the acute stage of intoxication. Associated symptoms are nausea, anorexia, and weight loss; school authorities report irritability and inattentiveness or even sudden loss of consciousness.

Although there is no evidence of any physiological dependence, the practice does seem to be extremely habituating. Some children may be driven to steal the glue in order to continue the habit. Many of those thus habituated share the belief that the practice may produce insanity and death, although there is no substantiation for this.

Diagnosis may be aided by the characteristic odor on the breath and by local inflammation of mucosa that has had direct contact with the glue.

From the preference of those practicing glue sniffing, it seems that toluene is the active substance of choice. A study of physical and psychological factors in 27 such children reported depression and a passive-aggressive manner of relating to peers and authority figures in all. The majority were Spanish-American of low socioeconomic status and with histories of delinquency of other forms. It was felt that the specific habit alleviated anxiety connected with sexual and aggressive drives. No positive laboratory or physical findings were reported.

There seems to be little question that a physiological adaptation occurs in that more and more of the substance is required to produce the euphoriant and exhilarating effects which pass into disorientation and coma. Unquestionably, a psychological dependence develops, so that just to remove sources of glue is insufficient treatment. Such people require a thorough psychiatric study, including investigation of the home and probably in most cases the development of a family treatment plan.

Other sniffing. Other forms of drug dependence involving sniffing include inhalation of gasoline vapor (usually brought to light because of vivid visual hallucinations), the use of pure toluene, sniffing of ether, and sniffing of lighter fluid. At times other organic solvents—lacquers, paint thinners, and enamels—have been used by various subjects.

Marihuana

This drug is known by other names, such as hashish, charas, bhang, and ganja. It is found in the cannabis plant and is often referred to as "pot" in North America. Cigarettes made from dried marihuana blossoms ("reefers") are smoked for their exhilarating and intoxicating effect. In this country, as in parts of Europe, marihuana smoking is seen in increased incidence among teen-agers and young adults, many of whom are on the fringes of society and who seem to be expressing their defiance of social mores by seeking this intoxication. However, psychiatric syndromes and character disorders of all types are to be found in such people, and marihuana smoking is symptomatic of an intrapsychic as well as a social problem.

The International Police Organization (Interpol) has reported a marked increase in the amount of marihuana being smuggled from one country to another and has expressed concern that this may be a factor in the known increase in cocaine and heroin addiction. Indeed, among narcotic addicts it is commonly found that experiences with marihuana were the prelude to experimentation with opiates.

There is no physiological dependence developed to this substance. Subjects experience disorientation, hallucinations, and a loss of the sense of time. On examination, they may show drowsiness, tremor, some

ataxia, and nystagmus. There may be increased sensitivity to pain and touch, and many subjects are talkative and outgoing with other members of the group participating in the experience.

Overdosages are associated with depressive affect in some subjects, more obvious psychotic experiences, tachycardia, diarrhea, vomiting, and severe sweating.

Very little is known of the chemistry and pharmacology of marihuana, nor are serious physical effects recognized from its continued use. Perhaps it may be true to say that marihuana, like morphine, is less dangerous than barbiturates in terms of the intoxication of the individual. On the other hand, its effect on the individual's behavior, social conscience, and ambitions and its tendency to lead to other addictions cannot be ignored.

Cocaine

The chewing of coca leaves in South America dates back to prehistoric times. Used in its purified form by oral ingestion or as snuff or intravenously, cocaine addiction is rarely seen in this country. Apart from its relative unavailability, it can produce frightening hallucinations, which are greatly feared by addicts.

Cocaine provokes no physiological dependence, but a very high degree of psychological dependence is the rule. Initially, it is taken for the exhilarating effect, and mixed addictions to cocaine and opiates do occur.

Symptoms include nervousness and apprehension along with tremulousness. On examination, the patient may show tachycardia, hypertension, mydriasis, and needle marks over veins.

With large dosage, a toxic psychosis, including visual and auditory hallucinations, is liable to develop. Such patients may have tactile hallucinations of insects creeping over their skin (formication). Delusions of a paranoid nature may occur, and these people are liable to become violent. Withdrawal is accomplished easily in a cooperative patient because there is no abstinence syndrome, but relapse seems highly probable in the absence of thorough psychiatric intervention.

Psychedelic Drugs

The various substances that induce hallucinations and psychotic-like states are currently being used in large amounts in nonscientific settings. Lysergic acid diethylamide (LSD) is used in its pure state, and psychedelic substances have also been obtained from concoctions of morning glory seeds. Mescaline or peyote is obtained from dried cactus, and psilocybin from a mushroom. Acute toxic reactions with psychotic-like symptoms have also occurred following ingestion of stramonium and nutmeg.

Studies done by Isbell and colleagues showed that, on repeated administration, the LSD effect declined rapidly, all subjects showing tolerance within less than 7 days. Tolerance was lost 3 days after LSD was discontinued. Metabolic studies of these drugs have failed to explain their modes of action so far.

The subjects who indulge in these substances, alone or in group sessions, tend to be similar to those taking marihuana. Undoubtedly, the degree and type of drug effect is greatly influenced by the social situation and the expectations of the individual. However, there do appear to be specific effects, such as euphoria and thinking disturbance. Keeler stated that most individuals who seek the drug experience have a reaction like hypomania, with a preoccupation with their own thoughts and perceptions intense enough to have some of the quality of schizophrenic withdrawal. He described the subjects as verbalizing statements such as: "I am enjoying beautiful sensory experiences and am having magnificent thoughts and insight that I have not had before. I am intensely happy and in harmony with the universe." Studies of people who return again and again to the use of the drug indicate that they are seeking an experience that seems desirable to them by virtue of their own psychological makeup. In this sense they are different from those who show little interest in repeated use.

For such persons, these substances are habituating, although not creating any physiological dependence. In the great majority of subjects there are no psychotic experiences of a continuing type, but undesirable effects can occur. For example, a student took off all his clothes and plunged from an upper window to his death while apparently intoxicated with mescaline. Some subjects have described a feeling that they could fly while under the effect of this drug.

Farnsworth believes that people attracted to the hallucinogenic drugs are often those most likely to be harmed by them. They are reaching out to these substances because of awareness of personal problems. He goes on to describe the "hell experience" reported by various students as sensations of great fear, disintegration, and being overwhelmed. In his experience it is demonstrated beyond question that these drugs have the power to damage the individual psyche, indeed, to cripple it for life. He reported indications that habitual use of the drug led, in some individuals at least, to looseness in thinking and difficulty in communicating coherently.

The importance of these substances for experimental and therapeutic purposes cannot be denied, but their control seems highly desirable. Keeler summarized the situation, "Restriction does deprive some of a pleasant though hardly essential experience, but more importantly it protects others from serious injuries."

Amphetamines

Excessive intake of amphetamines and similar drugs for exhilarating effects has become a major problem in recent years. In various countries, legislative steps are being taken to control the supply of this medication. Patients frequently get caught up in a vicious cycle of self-administration of amphetamines combined with, and alternating with, barbiturates. Some begin as

sufferers from obesity seeking to reduce appetite, others start in group activity seeking a thrill, and some amphetamine abuse begins among those who feel the need to stay awake, such as truck drivers and students. Lemere described a high incidence of amphetamine addiction in Japan. Apparently, the substance was used extensively during World War II and was readily available after the war. He stated that chronic psychoses occurred in many of the addicts who used the drug over long periods of time and who showed experimental and clinical evidence of organic brain damage.

Before nasal inhalants were changed as to their contents, prisoners in penitentiaries would break them open and chew the wad of cellulose impregnated with amphetamines. Now the substance is usually taken in the form of pills ("pep pills," "goof balls"). Some teen-agers and young adults have used dissolved tablets for "mainlining" (intravenous injection) in spite of the fact that the needle often becomes blocked. The same is true of tablets of Dexedrine and ephedrine.

Characteristics. Tolerance to the drug develops and is accompanied by increasing feelings of tension, apprehension, insomnia, and anorexia. This often leads to the introduction of barbiturates to insure relaxation and sleep. Physical signs include tachycardia, hypertension, and mydriasis. The patient feels a state of stimulation which is followed by a let down feeling of fatigue and often depression. Although no true physiological dependence develops, many patients show much psychological dependence, feeling emotionally disabled and dulled when the medication is withdrawn. Overdosage of amphetamines is liable to be associated with hallucinatory, psychotic episodes and paranoid delusions.

Several authors have reported cases of dependence on phenmetrazine (Preludin) and diethylpropion (Tenuate, Tepanil), and associated paranoid states have been described.

Diagnosis. Diagnosis can be difficult. Many of these patients are very untruthful, and it is rare for them to volunteer details of their dependence. Chemical tests for amphetamines in urine and other body fluids are not entirely reliable but should be used to assist in making a diagnosis. The psychiatrist is well advised to retain a high level of suspicion for this condition when dealing with patients from susceptible groups, such as students and truck drivers. In particular, a combination of tension, anorexia, weight loss, restlessness, and paranoid ideation should suggest the possibility of toxic symptoms due to excessive use of one of these stimulant drugs. Aggressive and rebellious behavior on the part of a teen-ager should always arouse suspicion.

Management. Placing the patient in a hospital and observing him while taking care that he has no further access to drugs can be an important part of the management. A barbiturate abstinence syndrome may ap-

pear. Attempts should be made to discuss drug possibilities with the family. Hopefully, new regulations regarding control of these stimulating drugs will reduce the incidence of drug dependence and toxic symptoms presently being seen by psychiatrists.

New Drugs

Undoubtedly, new drugs of potential dependence will be introduced in the future with a fanfare of statements that they are nonaddicting, do not invite drug dependence, and are unassociated with development of tolerance. Thus, lulled into a sense of false security, physicians will utilize these new medications freely. The majority of patients will take them within the limited amounts prescribed and will have no trouble. A minority will seek to experience the tranquilizing or sedative effects. Eventually, the literature will reveal case reports of patients showing intoxication on the drug and an abstinence syndrome at the time of withdrawal. Then the manufacturer's literature will begin to carry statements such as, "Abrupt cessation after prolonged overdosage may, in some patients, produce withdrawal symptoms (e.g., convulsions, tremor, abdominal and muscle cramps, vomiting, sweating) similar to those seen with barbiturates, meprobamate, and Librium (chlordiazepoxide HCl)." Such a statement now accompanies packages of Valium.

It seems equally probable that future antidepressant and stimulating drugs will be abused by some people as a source of "kicks." The need for controls of drug manufacture and distribution is unlikely ever to end.

Suggested Cross References

Fundamental concepts of importance to the subject of addiction—specifically dependence, habituation, addiction, tolerance, and withdrawal—are discussed in Wikler's section on opioid addiction (Section 27.1). Alcoholism is discussed by Chafetz in Section 27.3. Chlordiazepoxide and meprobamate are also discussed in Denber's section on tranquilizers (Section 35.1), and amphetamine is discussed in Cole and Davis's section on the antidepressant and stimulating drugs (Section 35.2), both in Area G, on psychiatric treatment. The psychedelics and marijuana are discussed in Mandell and West's section on hallucinogens (Section 5.4) in Area B, on the basic behavioral sciences. Clinical syndromes due to bromide and barbiturate intoxication are also described in Hoff's section on brain disorders associated with toxins in Section 20.2. Treatment of some of the acute intoxications mentioned in this section is also discussed in Section 33.2, on psychiatric emergencies. For information regarding addictions of children see Freedman and Wilson's section (Section 41.7) in Area H, on child psychiatry.

Definition

Precise definition is the cornerstone of scientific effort and communication. Yet in the study of alcohol problems and alcoholism, which concerns members of many disciplines, there is no scarcity of definitions, although there is a lack of agreement and communication.

The standard nomenclature of the American Psychiatric Association includes alcoholism in the personality disorders—addiction category. Some have used the term “alcohol addiction”; others prefer “chronic alcoholism”; still others refer to “abnormal drinking,” “inebriety,” “problem drinking,” “alcoholism,” “pathological alcoholism,” or “alcohol problems.” In spite of the wide diversity of opinions and labels, Keller, among others, has pleaded that each writer explicitly and clearly state what he means. Keller went on to offer his own modification of the widely used World Health Organization definition, which states that “Alcoholism is a chronic behavioral disorder manifested by repeated drinking of alcoholic beverages in excess of the dietary and social uses of the community and to an extent that interferes with the drinker’s health or his social or economic function.”

Although widely quoted, this is a less than ideal definition for the following reasons: (1) The definition is descriptive and symptomatic rather than etiological. (2) The physiological, psychological, and social phenomena it embraces are integrated at varying levels, lending themselves to qualification. The fact that qualitative judgments must be made pushes the observer more in the direction of moralist than scientist. (3) The sociological aspect of the definition implies a greater concern with group deviance than with individual discomfort, signifying that much destruction from the use of alcohol must occur before difficulties can be noted.

Classifications. Jellinek attempted to illustrate the complexities of alcohol problems by devising a new classification of alcoholic persons in terms of “Alpha, Beta, Gamma, Delta, and Epsilon alcoholism.” “Alpha alcoholism” was described by Jellinek as “a purely psychological continual reliance on the effect of alcohol to relieve bodily or emotional pain.” Although society may view the drinking as beyond the norm because the time, place, amount, and effect are beyond the implied conventions, drinking in this group does not lead to uncontrolled drinking or an inability to abstain. Most consequences of the drinking pattern involve the family: financial or work crises, lowered productivity, and perhaps nutritional deficiencies. Withdrawal disturbances and signs of progression are not in evidence. Alpha alcoholism is viewed not as a disease entity *per se* but as a medicinal use of alcohol, taken to deal symptomatically with underlying pathological discomfort. Jellinek admitted that often there is progression to more

27.3 ADDICTIONS. III: ALCOHOLISM

MORRIS E. CHAFETZ, M.D.

The attraction of man to alcohol has existed throughout history. Countless fruits have produced, by countless techniques, many forms of alcoholic beverages. Always, too much of this good thing led to excesses and inebriety, and the struggle within society for and against the use of alcohol was waged.

Primitive societies early identified intoxication with religious fervor. During intoxication, primitive man expanded the limits of his reality, gained a sense of increased power, obtained ecstatic sensations, and was able to converse with his gods. But even as alcohol freed him from the bonds of his inner self and his outer reality, the transcendental state of intoxication caused a decreased capacity for battle and an increased vulnerability to attack. Therefore, laws and limits had to be introduced. Since the use of alcohol needed to be controlled, perhaps in the earliest dawnings of our ancestry, the first moral attitudes for and against drinking arose, reflecting themselves in a concern for alcohol problems and alcoholism.

The confusion engendered by moral attitudes and their effects on definitions of alcoholism has always plagued interested observers and even today prevents our reaching more complete understanding of alcoholism.

serious drinking patterns, and he further complicated his definition by noting that Alpha alcoholism can often be referred to as "problem drinking" or as implying a physical dependence on alcohol.

"Beta alcoholism" represents to Jellinek that form of alcoholism wherein physical complications often occur—such as polyneuropathy, gastritis, and liver cirrhosis—but where there is no physical or psychological dependence on alcohol. Here Jellinek was admittedly describing certain societies in which nutritional deficiencies are common and heavy alcohol use is part of social custom. Withdrawal symptoms are uncommon among this group.

"Gamma alcoholism" represents a most serious form of alcoholism. Here is seen increased tissue tolerance to alcohol, withdrawal symptoms, and loss of control. Gamma alcoholism indicates a definite progression from psychological to physical dependence associated with marked behavioral alterations. The intrapersonal and interpersonal destructive changes in this form of alcoholism are great; this form of alcoholism is said to represent the patient population of alcoholism clinics and Alcoholics Anonymous groups in the United States.

"Delta alcoholism" is like Gamma alcoholism, except that the Delta alcoholic person cannot refrain from partaking of alcohol even for a day or two.

Unfortunately, Jellinek's attempt to bring order out of disorder tends to isolate and categorize alcoholic persons further into static groups, and his classification system is not widely used.

Determining illness. The question of changing the determinants of illness is not as simple as it seems, and large treatises could be written on this subject alone. Many individuals believe that, from a pragmatic view of determining who is ill and who needs help, one of two situations must exist: (1) the individual recognizes some discomfort, dysfunction, or difference within himself for which he seeks correction, or (2) society recognizes some dysfunction, difference, or deviance in an individual or group and insists on correction. By such a practical division, the individual who has, for example, actively hallucinated for years but who is not uncomfortable or unable to function as a result of this and whose condition is accepted by society is not deemed ill. He is designated as ill at that moment when he or his society recognizes the discomfort.

The attitude expressed above is also present in views about alcoholism. The use of alcohol has been an integral part of most societies during their recorded histories, and there is no evidence to indicate that drinking alcohol will, in the foreseeable future, disappear. Since the consumption of alcoholic beverages is common to many and since the response to alcohol is so variable from individual to individual and even within the same individual from time to time, the exact point on the drinking continuum between health and illness cannot be determined.

Proposed definition. Here, alcoholism will be defined as a chronic behavioral disorder manifested by an undue preoccupation with alcohol and its use to the detriment of physical and mental health, by loss of control when drinking is begun, and by a self-destructive attitude in dealing with personal relationships and life situations. Alcoholism results from a disturbance and deprivation in early life experiences and the associated related alterations in basic physicochemical responsiveness, from the identification by the alcoholic person with significant figures who deal with life problems through an unhealthy preoccupation with alcohol, and from a sociocultural milieu that causes ambivalence, conflict, and guilt in the use of alcohol.

This definition provides the latitude necessary for a more complete understanding of alcohol use and alcoholism. For example, the emphasis on the chronic behavioral aspect in the definition does not allow the designation of alcoholism for the occasional unhealthy use of alcoholic beverages common to most drinkers at one time or another. At the same time, the definition of *chronic* is not determined by a set number of responses, since the entire philosophy underlying the determination of alcohol problems at the present stage of knowledge must be delineated on an individual basis.

The fact that the definition focuses on *preoccupation* rather than on amount or excesses is also important. Too often the heavy emphasis on excessive use of alcohol is a means of self-protection for the social system devising the criteria of alcoholism. What is excessive to one individual at one time may not be excessive to another or to the same individual at another time. In this sense, the militant teetotaler who has never tasted alcohol but who is constantly uncomfortable in the presence of alcohol or others using it is preoccupied to a sufficient degree to produce his own dysfunction and difference and could also be thought of as suffering an alcohol problem. (The psychiatrically sophisticated will see the analogy to phobic impairments of function in other psychiatric syndromes.) The few militant teetotalers who have permitted themselves to be studied by this writer report their common fear that, were they to start drinking, they would be unable to stop.

The reference to loss of control in the definition describes both psychological and physiological responses. The militant teetotaler or moralist who destroys the property of others or infringes on their rights in order to impose his fear of alcohol has lost as much control as the individual who, under the influence of alcohol, responds behaviorally in a pattern inconsistent with his usual behavior. Intoxication does not have to occur, and often does not, in individuals who lose control, although the drugless intoxication of the reformer is often not very different from those intoxicated by alcohol.

The self-destructive component of the definition is

important. Man is a social animal, and his ability to relate emotionally to others is a measure of his psychological development. Furthermore, his ability to function, take care of himself, and adapt to his environmental stresses and needs constantly tests his emotional stability. If, for example, he withdraws and spurns contact with others, does not function and produce, cannot respond to the frustrations common to existence, craving only immediate gratifications, he is emotionally underdeveloped and unstable. When he responds behaviorally so that all efforts of progress or improvement toward emotional stability are thwarted or further potential for emotional growth and life is threatened, his behavior is considered self-destructive. Alcohol can further a pattern of self-destructive responses.

Etiological implication. In terms of the etiological components of the definition, the disturbance and deprivation of early life experiences are common in, but not exclusive to, alcohol problems. The stage of emotional development at which the disturbance and deprivation occur determines the severity of the emotional maladaptation that occurs as well as the potential for correction. It seems strange in an enlightened age to have to restate the fact that the mind-body dichotomy does not exist but that emotional responses have their associated physiological responses and vice versa and that, consequently, disturbances involving early deprivation produce altered physicochemical responses in an individual. Just as environmental influences physically affect the direction and development of genetic matrices, so does the individual respond psychologically. The countless highly individualized events that mold our personalities also result in highly individualized physicochemical patterns. This is true whether or not one is considering alcohol problems, other psychiatric disorders, or normal development.

From this vantage point it is not difficult to see that there is no single personality configuration in alcoholism but rather, as experience has shown, alcohol problems may and do occur in any and all types of psychological disorder. Therefore, alcohol problems or, considered collectively, alcoholism, develops not as an isolated phenomenon but as one manifestation in a total complex of disturbances.

The unhealthy preoccupation with alcohol as a manifestation of problems of inner or outer adjustment is dependent on two other factors. The first is that the individual depends on an identification with a significant person whose reliance on alcohol in order to deal with life problems is unhealthy. It is not necessary to elaborate on the common psychological fact that the young learn both healthy and unhealthy patterns of response through the process of identification. For that reason, study after study has shown that offspring drink like their parents: heavy drinkers produce heavy drinking children, abstainers produce abstainers, and moderate drinkers produce moderate

drinkers. The high incidence of alcohol problems in the family constellations of alcoholic persons further confirms these observations.

The second factor leading to unhealthy preoccupation with alcohol concerns the particular cultural attitude toward alcohol and its use. There are many cultures where alcohol is used early and often, and these cultures do not by any definition (except those that contend any imbibing of alcoholic beverages indicates a problem) suffer any significant alcoholism. The fact that societies exist that use alcohol and do not suffer alcohol problems does not mean that these societies do not contain their share of emotional problems or abnormal physicochemical responses. What it does indicate is that these societies produce environments where problems are manifested by other symptoms or means rather than by unhealthy alcohol preoccupation.

Experiences to date emphasize the idea that in cultures where there is marked *ambivalence* regarding the value and place of alcohol, where drinking is done in conflict and in guilt, the potential of incorporating an unhealthy preoccupation with alcohol into a troubled psychophysical adaption pattern is great. Where drinking is unambivalently integrated into the socialization process of a society, where it is intimately interrelated with moral symbolism and repeatedly practiced as a group activity, conflict is minimal and so is alcoholism.

Epidemiology and Social Consequences

Beyond the problems of definition lie the social consequences of alcoholism, which are extensive. The obvious deterioration of physical and social integrity of the skid row habitué is well known. Much less apparent are the effects of alcoholism on persons in other socioeconomic settings from which the majority of such persons are drawn: the loss of income, the loss of potential and of productivity, the rupture of families, the physical impairments, and the contagion factor hinted at above. The enormous cost to the community of alcohol problems is inestimable. Courts, hospitals, clinics, agencies, industries, families, and individuals are constantly expending energies and resources on behalf of alcoholic persons.

The formal resolution of the Committee on Alcoholism of the Council of Mental Health of the American Medical Association in 1956 stated that "the profession in general recognizes this syndrome of alcoholism as an illness which justifiably should have the attention of physicians." This reflects the sensitivity of the subject, for there are few conditions on which physicians have had to vote so late in the game as on whether this problem is the responsibility of the medical profession. The American Psychiatric Association in 1965 issued a position statement on alcoholism, taking the stand that psychiatrists and other physicians should extend to alcoholic persons the same care afforded to other ill persons. These attitudes of the

care-taking professions, which merely reflect the attitudes of the public at large, emphasize the difficulties of ascertaining accurate information about the incidence of alcoholism. Moralism, disdain, and disgust toward alcoholic persons will always cloud attempts at deriving a clear picture of alcohol problems.

Incidence. Of 80 million users of alcohol in this country, it is estimated that there are 4.5 to 5 million alcoholic persons. No true census is available, and epidemiological studies are rare. Most figures are based on the Jellinek formula (discredited by Jellinek himself) or on fancy or fright, depending on the motives of the issuing authority. A further complication of alcohol problems is the role played by legal statutes. The Federal Bureau of Investigation, for example, in its Uniform Crime Reports, finds that the crime of drunkenness represents more than 40 per cent of all arrests and is, therefore, the nation's major single crime. The State of Massachusetts arrests and commits to jail more people for the crime of drunkenness than for all other crimes combined. As many as a third of the patient populations of tuberculosis sanatoriums and mental hospitals suffer from alcoholism as a complicating diagnosis of all admissions. Chronic disease institutions, public welfare recipients, delinquents and their parents, divorcees, sex offenders, and others in similar categories consistently provide a higher percentage of alcoholic persons than should be expected in terms of the general population.

The problem of learning about the true incidence of alcohol problems is best illustrated by examining the ratio of male to female alcoholic persons. The most commonly quoted figure is $5\frac{1}{2}$ to 1. However, recent clinical observations suggest that more women than men are seeking treatment. The impression that there are more male than female alcoholic persons could arise from the easier detection of the illness in men. Men cannot hide as easily as women, since they must go out into the world and to their occupations, where society may recognize a disturbance or dysfunction due to alcohol; a woman, however, may remain protected in her home and for long periods escape social or even family detection. Families, friends, business associates, physicians, and others protect the patient against recognizing a difficulty until the destructive consequences are so great that deception is no longer possible. For this reason, it is hard to say how true the male to female ratio figures are. Also, since the climate surrounding alcohol problems is finally changing, one cannot say whether there is a rising incidence of it or whether people are asking for help more readily in an understanding environment.

Moralism and alcoholism. The recognition of the moral overtones in what is really a medical-social issue has an ancient history. As long ago as 2285 B. C., a man was banished from China for creating an intoxicating drink from rice. In the 16th century, Sebastian Franck reminded his readers in

On the Horrible Vice of Drunkenness that "More men are drowned in the glass than in the sea." Thomas Trotter, the Edinburgh physician who in 1778 completed a study on the disorder of alcoholism, wrote: "Mankind, ever in pursuit of pleasure, have reluctantly admitted into the catalogue of their diseases, those evils which were the immediate offspring of their luxuries. Such a reserve is indeed natural to the human mind; for of all deviations from the paths of duty, there are none that so forcibly impeach their pretensions to the character of rational beings as the inordinate use of spiritous liquors."

In 1784, Dr. Benjamin Rush published *An Inquiry into the Effects of Ardent Spirits on the Human Body and Mind*, in which he concluded that there were no beneficial effects to be derived from alcoholic beverages. He implied from the beginning that there was a direct relationship between individual control of drinking and personal character and morals. This conclusion was emphasized by the strict regulations imposed against the sale of alcoholic beverages to the irresponsible individuals of low status—indentured servants, Indians, and ex-convicts. The use of alcohol was thought to breed dissolute habits and threaten the spiritual life of individuals and of communities, although no voice was raised against the alcohol trade itself, which helped build the great fortunes and power of our important Colonial families.

About 1825 the American temperance movement became active. At first its efforts were directed against immoderate use of alcoholic beverages and abstinence from ardent spirits, but by 1850 alcohol in any form was identified with Satan, and total abstinence was demanded on moral grounds for all who aspired to the "good life." Thereafter, the battle lines were drawn between the organized temperance movement, supported by many church leaders, and the alcoholic beverage industry, which had organized to defend its position in the middle 1860's. As a result of this struggle, the problems of the individual with alcohol difficulties were submerged.

Moralistic pronouncements from the clergy and others only served to isolate further the person who suffered from alcoholism. The public could only deduce that, since the authorities contended that the excessive use of alcohol inevitably induced physical deterioration and disease, the individual had two choices: to abstain completely or to drink under control. The fact that for some individuals drinking under control was impossible was ignored, and any individual who sought help only to relapse was considered insincere in his attempts to lead a wholesome life. The conclusion of Dr. Thomas Trotter in 1804 that alcoholism was a disease of psychogenic origin was ignored. He said, "In medical language, I consider drunkenness, strictly speaking, to be a disease; produced by a remote cause, giving birth to actions and movements in the living body, that disorder the functions of health." He went on to write: "It is to be remembered that a bodily infirmity is not the only thing to be corrected. The habit of drunkenness is a disease of the mind."

In 1830, the Connecticut Medical Society recommended the establishment of an asylum for the care and treatment of inebriates, and 3 years later the superintendent of the state hospital in Worcester, Massachusetts, made a similar recommendation. In Binghamton, New York, in 1864, the New York State Inebriate Asylum was opened, financed by private funds. But these efforts were few and far between, meeting with the approval of only a limited number of physicians and eliciting almost no support from the public.

The great movement of the 19th century in this field was that of the Washingtonians. Begun by a group of habitual drinkers in 1840 who decided to take the pledge of abstinence, the effort spread with great enthusiasm and emotionalism within months throughout the United States, with thousands joining. Even people who had no drinking problems took part, but the movement gradually disappeared. In its wake, however, the Washingtonians left "homes" in several cities where the medical side of inebriety could be treated. Unlike the practice in state mental institutions, patients were treated

without restraints, were allowed to go about the city, and were regarded as men of honor rather than as degenerates.

In 1870, a number of state hospital superintendents and other physicians interested in alcohol problems founded the Association for the Study of Inebriety, leading to establishment in 1876 of the *Quarterly Journal of Inebriety*.

The early years of the 20th century saw the establishment of the Emmanuel Movement and the Peabody program for reeducating alcoholics. But the period of national prohibition between 1920 and 1933 produced a situation where the alcoholic person, lost in the turmoil, became the responsibility primarily of county jails and psychopathic hospitals, and ancient prejudices again impeded scientific effort.

Nature of Alcohol

Ethyl alcohol. Whenever people talk about alcoholic beverages, they are, in effect, talking about ethyl alcohol. Although a large number of compounds may be chemically designated as alcohols, ethyl alcohol is the common denominator of beverage alcohol, whether it is wine, beer, mead, or whiskey. Other alcohols are less suitable because they are not so rapidly oxidized by the body. Methyl or wood alcohol, for example, is no more intoxicating than ethyl alcohol, but, because its oxidation rate is so slow, periods of intoxication are greater, as is its potential for cumulative effects. Furthermore, the products of metabolism of ethyl alcohol are harmless to the body, but the oxidation of small amounts of methyl alcohol produces toxic substances that damage nerves, especially the optic nerve, leading to blindness. An amount of ethyl alcohol that disappears from the body of a drinker in 1 day would be present for a week if methyl alcohol were substituted.

Ethyl alcohol in its pure state is a colorless liquid with little odor but a strong stinging taste. The characteristic alcohol breath comes from the odor of the aromatic oils resulting from an alcohol and water mixture rather than from the alcohol itself. Most alcoholic beverages contain at most about 50 per cent pure ethyl alcohol.

Physiological effects of alcohol. The fate of alcohol in the body is an interesting phenomenon. Alcohol lifted to the lips, from the initial sniff, gets into the blood stream in small amounts through the lungs. Most foodstuffs must be first digested by elaborate chemical means before they can be absorbed and exert their influence—not alcohol. Alcohol can only provide its effect by entering the blood stream and being transported to the brain, where it brings its major influence to bear. No matter how great the amount, unabsorbed alcohol in the alimentary tract is without local effect. At what speed the alcohol leaves the stomach and small intestine to be absorbed depends on many factors: the amount and type of food in the stomach, the type of beverage consumed and its concentration, the circumstances under which it is being drunk, the emotional state of the drinker, and his individual constitutional state.

Mechanics of absorption. Foods in the stomach, especially fats and proteins, are excellent delayers of

alcohol absorption. Experienced drinkers know only too well the differing effects the same amount of alcohol causes with and without food in the stomach. Drinking water before partaking of alcohol will increase absorption, as will carbon dioxide; for that reason, champagnes are notorious for causing rapid and heightened effects. Beer contains foodstuffs that delay absorption, and for that reason more beer is consumed to achieve an effect.

The body has certain protective devices against being inundated by alcohol. For example, again unlike other foodstuffs, alcohol can be absorbed into the blood stream directly from the stomach. No more than 20 per cent of the alcohol can reach the blood from the stomach—otherwise the effects would be disastrous and dangerous. If the concentration of alcohol becomes too high in the stomach, mucus is then secreted, and the pyloric valve closes. This slows absorption and prevents the alcohol from passing into the small intestine, where no important restraints to absorption are available. Thus, in the imbibitor who has consumed immoderate quantities, a large amount of alcohol remains unabsorbed for hours. Further, the pylorospasm often results in nausea and vomiting and the production of an unpleasant memory not at all conducive to further excessive drinking.

Once alcohol is absorbed into the blood stream, it is distributed to all the tissues of the body. Since it is uniformly dissolved in the water of the body, those tissues containing a high proportion of water receive a high concentration of alcohol. However, since human bodies contain essentially similar amounts of various tissues and water, it is possible with some accuracy to predict, from the concentration of alcohol in the blood, the total amount of alcohol present in the whole body.

The National Safety Council has adopted the concentration of 0.15 per cent of alcohol in the blood as evidence of intoxication with respect to the operation of a motor vehicle. Most people would show definite and obvious signs of intoxication at 0.25 per cent of blood alcohol concentration—a level requiring in the average adult the downing of approximately 12 ounces of whiskey within a few hours. What these measures of concentration do not indicate is what the behavioral responses of the individual will be to a given concentration at a given point in time.

The attention paid to the mechanics of absorption is important because alcohol is more intoxicating when it is being absorbed than when it is being destroyed or oxidized. For this reason, the rate of absorption has a direct bearing on intoxicating responses. All things being equal, the same amount of alcohol sipped slowly will have a much lowered effect than when gulped rapidly.

Mechanics of elimination. Immediately following absorption, destruction and elimination begin. The kidneys and lungs excrete about one tenth of the total alcohol ingested unchanged; the rest undergoes

oxidation. Although other foodstuffs liberate their chemical energy in relation to the energy needs of the body, the rate of oxidation of alcohol is independent of these requirements and proceeds at a fairly constant rate. Thus, the average person oxidizes $\frac{3}{4}$ ounce of whiskey an hour. If his rate of sipping is equivalent, he does not accumulate alcohol in the body or become intoxicated.

Alcohol's oxidation provides heat and work energy, but its calories cannot be stored. However, because excessive consumers receive so many calories as a consequence of their alcohol intake, other foods go by the board. Although the alcoholic person may satisfy his calorie requirements, he ignores his nutritional needs. The ultimate results are nerve degeneration and deficiency diseases. Previously, many deficiency diseases common to alcoholic persons were thought to be due to direct damage by alcohol on bodily tissues.

No method yet known can hasten the disappearance of alcohol from the body beyond the leisurely pace noted above.

Effects on the brain. The prime action of alcohol that concerns us here is its action on the brain, where it is a central nervous system depressant similar to other anesthetics. Those parts of the brain affected and the degree of impairment depend on the concentration of alcohol in the body, the experience of the drinker, and the surroundings in which the drinking takes place. Whatever part of the brain is most anesthetized, the disturbed behavior is manifested in those organs controlled by the affected brain part—by thick speech, clumsy movements, and poor coordination.

At a level of 0.05 per cent of alcohol in the blood, more recently learned responses are depressed, diminishing inhibition and restraint and coloring judgment. At a level of 0.10 per cent, older brain centers are narcotized, and motor and speech activity is impaired somewhat. To varying degrees, these are the states people are seeking when they drink to be stimulated. The stimulation is illusory and is the result of the altered quality of behavior produced when alcohol removes prevailing inhibitions and restraints. The world looks brighter, and a splash of color is applied to a sometimes stark reality. The harshness of self-judgment and criticism is for a moment removed, and one's fellow man looks less threatening.

However, at 0.20 per cent, impairment of function is more gross: the motor area of the brain is profoundly affected. The world is viewed from the horizontal. At 0.30 per cent, sensory perception is severely impaired, and the person is stuporous. At 0.40 per cent, perception is obliterated, coma exists, and the individual is anesthetized. At 0.60 or 0.70 per cent, those primitive centers of the brain controlling breathing and heart beat are affected, and death ensues.

Throughout this entire phylogenetic retrogression of the brain from its most recent to its most ancient

centers of development, the concentrations of alcohol in the body are much too low to cause any direct permanent damage to the tissues. What is seen is a functional effect of alcohol on reversible brain activity; when the alcohol disappears, so does the effect—except at the 0.60 to 0.70 level.

Other physiological effects. Many alcoholic persons are intoxicated much of the time, but alcoholism is not the only effect of intoxication. Prolonged copious use of alcohol may produce withdrawal symptoms. Because alcohol affects the pituitary gland, chronic states of intoxication may result in disturbances of growth and development, sexual cycles, and mineral and water balance.

The liver is affected by alcohol and is the main site for detoxification of alcohol in its metabolism. A reversible fatty infiltration of the liver is thought to occur with alcohol ingestion. What relation, if any, this plays in the production of liver cirrhosis is not yet known. The tremendous shift of water from within the cells to the extracellular spaces and the corresponding alteration in salts distribution may also be responsible for a variety of bodily malfunctions.

Chronic states of intoxication, a state of physiological and psychological disequilibrium, produce not only a disturbance of the external environment, but a disorganization and disruption of the internal physiological environment. The prolonged disturbance of homeostatic mechanisms in the chronically intoxicated may result in persistent damage to tissues and organs of the body.

Alcoholic Psychoses

The relation between alcoholism and the implied alcoholic psychoses is not so clear as was formerly assumed. In many cases alcohol is merely the means by which severe long standing personality problems are brought to the surface. In other situations, the interplay of psychological and physiological factors is such that the matter becomes more complex. In Korsakoff's syndrome and chronic alcoholic deterioration, for example, the psychosis is not due to the toxic effects of alcohol per se but may be due to a deficiency of thiamine. Even here, the underlying personality structure colors the picture. Alcoholism may be but a symptom—a relatively obvious one—of a schizophrenic or manic-depressive psychosis.

Blackouts. Although the term is commonly used among alcoholic persons, the occurrence of blackouts is infrequent in the total alcoholic population. Blackouts refers to a *total* amnesic state the chronic sufferers of alcoholism may in time develop. The patient has no recall of his activities or behavior when he has blacked out, although to the disinterested observer the individual is reasonably intact. Whether this phenomenon is a drug-induced amnesia attack or an acute dissociative response is unclear. One patient, a successful pharmacist from the Midwest, once, after drinking heavily, "came to" in a hotel in Los Angeles

surrounded by "friends" he had met on the way and whose transportation and accommodations he had paid for. He could never remember having met them, and they were unaware that he was heavily under the influence of alcohol.

Pathological intoxication. This term is seldom used. It was the rubric applied to a group of borderline patients who, even with a small intake of alcohol, would develop a transitory mental state much more severe than ordinary intoxication. The onset of pathological intoxication is dramatic and sudden. Consciousness is impaired. The individual is confused and disoriented and suffers illusions, transitory delusions, and hallucinations of sight. There is greatly increased activity, impulsive and aggressive, often to the point of destructiveness. Rage, anxiety, and depression are the emotional components, and suicidal attempts are frequent. This disorder may last for a few moments, a day, or more. It terminates in a prolonged period of sleep, with amnesia for the episode on awakening. The general consensus is that persons with hysterical or epileptoid temperaments are more prone to these outbursts; they have high levels of anxiety and tension, and alcohol may cause sufficient disorganization and loss of control to release aggressive impulses.

Delirium tremens. Delirium tremens (D.T.'s) is an acute psychotic state usually occurring after a prolonged, copious, and severe period of drinking. Delirium tremens is rarely seen in people under the age of 30 or in those who have not suffered serious alcoholism for 3 to 5 years. An attack was once thought to be the result of a sudden deprivation of alcohol, but this is not entirely true. A lowering of the blood alcohol level is known to produce delirium tremens, as do acute injuries or infections. The delirium is usually preceded by restlessness, irritability, an aversion to food, tremulousness, and disturbed sleep with terrifying dreams. Occasional illusions or hallucinations become more frequent. The patient is terrified; there may be threatening insects and animals, visual hallucinations of movement, and walking animals from which the patient, in his frantic terror, attempts to escape. Tactile and olfactory hallucinations—bugs crawling on him or gases being pumped into his room—are frequent. Auditory hallucinations, on the other hand, are rare. Although the mood of apprehension, irritability, and terror is usual, euphoria, silliness, or amusement with the telling of tall tales may at times be seen. Confusion with disorientation for time and place is common; attention is fleeting; motor activity is marked and sleep impossible.

Physical examination reveals congestion of conjunctivae and face, with dilated pupils slow to react. A coarse tremor is almost always present and is increased by muscular tension. A tremulous tongue, lips, and face are often seen in fully developed cases. The pulse is rapid, irregular, and weak. Temperature

is elevated, the skin moist, perspiration free, reflexes heightened, and speech indistinct. Epileptiform seizures may occur.

Etiology and course. The nature of the factors that produce delirium tremens is not definitely known, but the condition is thought to be due to a disturbed metabolic state. Pathological changes of both a degenerative and inflammatory nature may be seen with an edematous brain, degeneration of nerve cells, and an increase of glia with some round cell infiltration. Punctuate hemorrhages and degeneration of myelin sheaths are frequent findings.

The course of delirium tremens usually runs 3 to 10 days, with recovery preceded by prolonged sleep, clearer consciousness, and disappearance of hallucinations (at night, brief periods of delirium may recur). Prognosis depends on the physical status of the patient and the presence or absence of concurrent disease. Patients with delirium tremens either recover, die from heart failure and pneumonia, or go on into a Korsakoff's psychosis.

Treatment. The treatment of delirium tremens involves withdrawal of alcohol and placing the patient in bed under excellent nursing conditions. Constant reassurance and the avoidance of physical restraints are most advisable. Morphine should be avoided. Many a patient has died struggling against bodily restraints or the effects of deep sedation. In this writer's experience, 8 to 12 cc. of paraldehyde every 6 hours (reducing the paraldehyde dosage gradually as necessary) with 25 to 50 mg. of chlorpromazine (Thorazine) three or four times a day is the best combination for producing calm and sleep in the delirious alcoholic patient. Nutritional needs must be carefully tended to with a high caloric, high carbohydrate diet supplemented by multivitamins. Care has to be directed toward proper electrolyte-fluid balance. Emphasis on the need for first rate nursing care cannot be stressed enough.

Acute alcoholic hallucinosis. The prevailing view is that this condition represents a liberation of an underlying personality disorder as a consequence of alcoholic intake. Many observers see a close relation to schizophrenia, and some believe this disorder is a schizophrenic reaction released by alcohol. Patients who have suffered chronic alcoholic hallucinosis have in time become obviously schizophrenic.

As with delirium tremens, acute alcoholic hallucinosis usually follows a prolonged drinking bout. In contrast to the visual hallucinations and clouded consciousness of delirium tremens, in this reaction auditory hallucinations of a threatening nature appear in a clear sensorium. In men, the voices of the hallucination commonly accuse or threaten the patient with homosexual attack; in women, the accusation and threat commonly involve promiscuity. Although illusions and olfactory hallucinations are common, visual hallucinations are rare. Ideas of reference and the acquisition of an elaborated delusional system are

frequent, with the patient often responding to his ideas. Often the patient tries to involve the law in his defense or use other means of protection against the terrifying attacks. Although hallucinating, the patient is oriented to time and place, fits his hallucinations and delusions into his real environment, and, even after he recovers, can recall vividly the events, feelings, and ideas of the psychotic episode. The mood of the patient is one of apprehension and fear, frequently accompanied by anger or depression. Suicidal attempts are common.

The treatment of alcoholic hallucinosis is to hospitalize the patient, withdraw alcohol, and provide medication to calm the patient. Thorazine, trifluoperazine (Stelazine), and antidepressants are useful, depending on the mood and behavior of the patient. Adequate nutrition and vitamins should be supplied.

The usual course runs 5 days to a month, but recurrences are common if alcohol is resorted to again. Korsakoff's syndrome rarely follows alcoholic hallucinosis, but frank schizophrenia, as noted, is common.

Alcoholic paranoia. This category represents another attempt to emphasize the alcoholic complication instead of the larger underlying problem. Patients who have been so diagnosed are those who never in their premorbid period established meaningful heterosexual relationships and show the same impairment of personality development and resultant psychopathological processes seen in other paranoid psychoses. Alcohol use weakens repression, and forbidden homosexual impulses rise to the surface and are defended against by a paranoid delusional system.

The clinical picture is characterized by delusions of jealousy, associated with suspicion and distrust. Projection is intense, and people in the environment are accused of that which is stirring in the patient. Questions of his own masculine role are often intensified by alcohol-induced impotence, and a panic-like state frequently occurs.

The prognosis is not good, although the patient is more comfortable and less delusional when hospitalized. Return to the original environment results in a recurrence of symptoms in most cases.

Wernicke's syndrome. Wernicke's syndrome is a rare, although once common, condition mainly seen in chronic alcoholic patients. It is due to vitamin and other nutritional deficiencies especially thiamine. It begins with delirium and consists of ophthalmoplegia, memory loss, confabulation, apathy or apprehension, clouding of consciousness, ataxia, and, at times, coma. It results from neuronal and capillary lesions, particularly in the gray matter of the brain stem and structures near the third and fourth ventricles.

Korsakoff's syndrome. Described in 1887 by the Russian Sergei Korsakoff, this syndrome may or may not be preceded by an episode of delirium tremens. Korsakoff's syndrome consists of amnesia, confabulation or falsification of memory, disorientation as to time and place, and peripheral neuropathy. Although

generally accepted as a condition of chronic alcoholism, it is mainly the result of nutritional deficiency, especially of thiamine and niacin. The resultant degeneration is mainly in the cerebrum and peripheral nerves, in contrast to the brain stem destruction of Wernicke's syndrome. Often, signs of Korsakoff's syndrome are present with signs of Wernicke's disease or pellagra.

At first glance, the Korsakoff patient may appear clear, and the severity of his mental disturbance may not be apparent. Although he may be able to deal with immediate events, those requiring memory are beyond him. The memory loss is progressive, and he responds to his amnesia by a lightness of attitude and a confabulation based on fiction. The direction the fictions take can easily be suggested by leading questions and can vary from day to day. Disorientation as to time, misidentification of people, and a superficially jovial mood are common. The confabulation and mood are defenses against the patient's confronting himself with his defective functioning. The accompanying polyneuropathy is most marked in the lower limbs, with pain and tenderness over the nerve and with absent knee jerks.

Many patients lose their symptoms after 6 to 8 weeks and return to almost their former level of mental functioning. In others the syndrome is not completely reversible, improvement takes longer, and recovery of memory is not complete. Some patients always retain a certain degree of intellectual, emotional, and esthetic impairment. Neuropathy clears quickly and usually completely.

Treatment consists of the withdrawal of alcohol and the institution of a regime of 20 to 50 mg. of thiamine chloride daily for a few days, followed by powdered yeast in iced milk three times a day. A diet rich in all nutrients should be liberally provided. Rest for the symptoms of neuropathy is advisable.

Alcoholic deterioration. In some patients who have suffered from a prolonged period of chronic alcoholism, one begins to see a gradual disintegration of personality structure, with emotional lability, loss of control, and evidence of dementia. The cause of the structural damage is due to brain damage from avitaminosis rather than the direct toxic trauma of alcohol. The underlying pathological change is the result of a diffuse degeneration of nerve cells in the cerebral cortex. The symptoms are related to the underlying personality structure associated with the general findings of any dementia.

Personality Factors

As has been stated earlier, there is no single personality configuration in alcoholism, nor is there a predetermined course through which alcoholic sufferers pass. Although the literature contains many descriptions of the stages of alcoholism, these tend to describe a retrospective composite of clinical experi-

ences with a large number of patients; since such a group has had diverse features, common responses are filtered out, and a stage of alcoholism is born. The truth is that little or nothing is known about the natural history of alcoholism. Nothing is known about the rate of spontaneous remission, the number of patients who reach a level of disturbance with alcohol and become stable, the incidence of patients who have a violent onset and rush toward a disastrous end with the speed of a raging malignancy. Until recently, when scientists began a more systematic study of alcoholism, the field consisted to a large degree of unscientific pronouncements and dogmas, the results of which continue to hamper new studies. Research findings that dispute the established notions are attacked in many ways—the most damaging of which is the contention that, if the new findings against the preconceived notion do exist, the patient cannot have been a true alcoholic.

Bearing these limitations in mind and remembering that in any case each patient must be studied and understood as an individual problem, one may look at the two broad categories of alcoholic persons: the reactive and the addictive.

Reactive alcoholic persons. Patients designated as reactive alcoholic persons are those who appear to have become preoccupied with alcohol only after being overwhelmed by some external stress. The picture of the dejected, disappointed individual heading for alcohol to wipe away the ugliness that has arisen from without or from within him is familiar. Unfortunately, in many cases the temporary relief prevails, and avoidance of facing fear is prolonged. In other cases, the alcohol intensifies the depression, and the individual, unaware of the causes of the deepened depression, consumes greater amounts of alcohol. With prolonged use of increasingly greater amounts of alcohol, physiological dependence on it occurs, and the person continues to drink heavily to prevent withdrawal symptoms.

Other reactive alcoholic persons may use alcohol to blur perceptions in the presence of an emotionally threatening milieu—such as surrendering to a homosexual overture and blaming alcohol for the response—or to support a system of defenses where acting out of the alcoholic person's repressed conflicts is possible—the latently hostile and aggressive person may overtly manifest these feelings but be utterly unaware of his response.

The most common reactive situation leading to a preoccupation with alcohol is that found in individuals who need to break down psychological barriers, for example, the lawyer who must have a few drinks before he can address judge and jury.

In reactive alcoholic persons, retrospective examination of their life patterns generally reveals that premorbid adjustment has been reasonably satisfactory. They have fulfilled their obligations to their families, to themselves, and to society. Goals have been achieved in their educational pursuits, occupational efforts

have been rewarding and stable, and they have been useful members of a social order. Their histories reveal reasonable progress toward realistic goals. The usual unhealthy encounter with alcohol has a determinable onset, it runs a course consistent with great tension release, and termination of the bout is related to a great effort of control exercised by the individual. The reactive alcoholic person may have one or more such periods of alcoholic distress; he may, in some cases, get so sufficiently involved with his preoccupation with alcohol that no other part of his life is important.

Because of the stigma attached to alcohol-related conditions, meaningful help is not readily forthcoming. Society finds it all too easy to associate its own drinking behavior and responses with those of the reactive group. As a consequence, the person with a reactive alcohol problem must become so ill and so disturbed that his alcoholic state becomes overt and his difficulty sufficiently perverse to be recognizable.

Addictive alcoholic persons. The addictive alcoholic person, on the other hand, shows gross disturbances in his prealcoholic personality, with marked evidence of inadequate and unsatisfactory interpersonal relations. There have been poor adjustments to family or school. Goals are seldom reached and, if they are, only at the expense of unwarranted time and effort. Occupational instability is common. The rate of marriage is similar to that of nonalcoholic persons, but marital disintegration is uncommonly high in patients with addictive alcoholism. Patients in this category have been fascinated with alcohol from their first encounter; the onset of drinking bouts is indeterminate, without apparent reason, continuing until the individual is physically unable to continue. Most striking in the total pattern of responses is the self-destructive component. This self-destructive aspect in the addictive person pervades his entire existence, from his dealing with people and things to his dealing with himself and his immediate environment.

The addictive group is so self-destructive and so different in drinking behavior from the general responses of society that society finds it easy to label this group "alcoholics." The main impetus of efforts to control alcohol problems, therefore, is directed here. In other words, the more malignant the condition, the greater the deficits, the lesser the potential for recovery—it is in these areas that the greatest effort has been expended against alcoholism to date. To those individuals who are less disturbed, with fewer deficits and with a greater potential for recovery, care is denied by ignoring the problem until the destruction is great enough to fit the addictive image.

Interpersonal relationships. In describing the interpersonal relationships of alcoholic persons, writers often state that most alcoholic persons do not form emotional and meaningful relationships. This implies a goodness or poorness of interpersonal relationships, which is not the entire picture. Alcoholic persons form

relations, but they tend to be rigid and stereotyped and subjectively unrewarding. Discomforting feelings and responses are denied; aloofness, feelings of omnipotence, invulnerability, and a lack of dependency on others is common. An all consuming hostility, associated with an inability to achieve satisfactory sexual adjustment, and depression as the all pervading mood disturbance are frequent findings in people with alcohol problems. Most often, though, alcoholic persons do not get from the relationships they form just what they want, nor do they make others pleased, satisfied, or happy. These responses are related to the disturbance and deprivation early in life and the resultant object loss.

Psychosexual development. Object loss, dependent on the stage of psychosexual development during which it occurs, produces insatiable demands by the individual on his surroundings and the people who frequent it. During early life, object loss may result in primitive excessive demands that cannot be satisfied and interpersonal relationships that cannot succeed. At their failure, rejection is encountered, reawakening the feelings of the original loss and rejection. The intensity of these feelings is so great that an all consuming hostility threatens the individual, and he can only deal with this by a self-destructive (rather than murderous) pattern, one facet of which is his preoccupation with alcohol.

At later stages of psychosexual development, a less intense disturbance and self-destructive pattern is possible: only specific traumas reawaken feelings of deprivation and disturbance, with resulting self-limiting responses.

The gratification of sexual activity, the type of interpersonal relationships, the intensity of hostility, and the pervasiveness of the self-destructive effort are similarly related to the level of development at which the impediment to psychological growth occurred. In this way, the earliest deprivation can only be gratified by oral satisfaction through incorporation and destruction of the love object, instituting the need eventually to find another object. For this reason, people with alcohol problems look for love in whatever, wherever, or whoever will provide it. This has resulted in much homosexual fantasy and activity in the lives of patients, misleading theoreticians into incriminating homosexuality as the cause of alcoholism.

The mechanism of denial is a patient's manner of dealing with life by denying feelings of isolation and inferiority, the absence of self-respect, and lack of sexual satisfaction, along with a dependence on alcohol and other external agents for security and care. Alcohol becomes one external means by which the alcoholic person can easily but with fickleness achieve control over his feelings of fear, helplessness, and deprivation. The denial works most intensely to guard against depression.

Depression as the prevailing mood in alcoholism is not surprising. Object losses, isolation, anxieties, ungratified sexual impulses, unrealized goals, and thou-

sands of feelings, real and fantasied, plague the sufferer so that relief must be sought. Hopelessness, sadness, and feelings of futility, failure, and worthlessness are sporadically or continuously present. Depression becomes so unbearable at times that only a bout with alcohol or a more direct suicidal attempt is the outlet. For this and other reasons, relapses can and do occur in the most highly motivated and determined people.

Etiology

Psychoanalytic theories. Psychoanalytic formulations on alcoholism received their impetus from Freud, who first believed that alcoholism was the result of strong oral influences in childhood. Alcohol provides a mood alteration and a consequent redirection of thought processes, providing the impetus for regressive levels of thinking and for achieving gratification from thinking unrelated to logic. Alcohol hence provides an escape from reality. Jelliffe emphasized the escape theory by pointing to the "autoerotic ecstasy of dreaming" provided by alcohol, and Parland equated escape in alcoholism with escape in homosexuality.

Menninger advanced the self-destructive drive as the prime component of alcoholism. Addiction was considered the means used by those individuals who unconsciously have a powerful urge to destroy themselves, an urge derived from the child's feeling of having been betrayed by his parents. Menninger contended that the conflict involves the child's intense rage, in which he wishes to destroy his parents yet fears losing them. Later in life, alcohol becomes the means to achieve gratification and revenge: hostility experienced via antisocial behavior while under alcohol and the resultant sober punishment to alleviate guilt. Therefore, Menninger sees alcoholism as a form of chronic suicide, unconsciously employed to avert the greater self-destruction of the parents and ultimately oneself.

Knight formulated the psychodynamics of alcoholism as follows:

His [the alcoholic's] childhood experiences have given him a personality characterized by excessive demands for indulgence. These demands are doomed to frustration in the world of adults. He reacts to the frustration with intolerable disappointment and rage. The reaction impels him to hostile acts and wishes against the thwarting individuals for which he then feels guilty and punishes himself masochistically. As reassurance against guilt feelings and fears of dangerously destructive masochism and reality consequences of his behavior, he feels excessive need for affection and indulgence as proof of affection. Again, the excessive claims, doomed to frustration, arise, and the circle is complete. The use of alcohol as a pacifier for disappointment and rage, as a potent means of carrying out hostile impulses to spite his parents and friends, as a method of securing masochistic debasement, and as a symbolic gratification of the need for affection is now interweaving itself in the neurotic vicious cycle.

Knight sees as the family configuration an overindulgent and overprotective mother who tries to soothe the infant by repetitive patterns of oral gratification in the presence of an inconsistent father. The child, as a

result of overgratification, cannot develop self-control, reacting with rage when frustrated. This capacity for rage and oral pacification is intensified by an inconsistent father, who unpredictably gratifies at one time and denies at another. This pattern of dependency, rejection, and insatiable desire for indulgence becomes an intimate part of the personality, associated with profound feelings of inferiority and guilt. Puberty produces an intensification of masculine prowess, and drinking is identified as manly. Emotional conflict of any origin in these people results in an impulsive response to frustration, which causes rage and thereafter guilt, requiring masochistic repair, which is provided by the pharmacological effects of alcohol, reinforcing irresponsible behavior. The ultimate result is to feed back an insatiable desire to be cared for, frustration, and the continuance of an addictive cycle.

The McCords emphasized an inconsistent satisfaction of dependency needs in the family background with confusion in self-image and conflict over satisfaction of dependency in the personality. Their formulation also contains emphasis on the cultural pressure placed on the definition of sexual roles and the creation of a facade of independence. Alcoholism, according to the McCords, develops with the collapse of the false self-image and the "emergence of repressed dependent traits."

Lisansky discussed psychological predispositions to alcoholism and assumed that

...etiological conditions in very early life experience are not highly specific among individuals who later become alcoholics. ... So much frustration has been imposed by his social environment in early life that he is wounded psychologically and remains stunted or arrested in various aspects of ego growth and function.... The predisposed individual has developed the following traits with which he enters his adult years: (a) an intensely strong need, drive, impulse toward dependency; (b) weak and inadequate defense mechanisms against this excessive need, leading to, under certain conditions; (c) an intense dependence-independence conflict; there is also (d) a low degree of frustration or tension tolerance; and (e) unresolved love-hate ambivalences.

Adler attributed the cause of addiction to powerful feelings of inferiority related to a perpetual state of insecurity and a desire to escape responsibility. An alcoholic addiction may be heralded, according to Adler, by marked shyness, a preference for isolation, impatience, irritability, anxiety, depression, hypersensitivity, and sexual inadequacy. Adler incriminated overindulgence and excessive coddling, leading to an inability to face the frustrations of adulthood, and the subsequent use of alcohol as a method of countering the demands of society.

Rado considered any drug craving as a manifestation of a single disease, pharmacothymia. Rado believed that certain individuals contained the potential to respond actively to the pleasurable effects of a drug. Therefore, he believed that it was not the drug but the impulse to use it that made certain individuals, who respond to the frustrations of life by great tension and

heightened intolerance to pain, resort to the use of alcohol. Rado stressed that alcohol provides a magical effect that brings about an increase in self-esteem and mood. As he writes,

A magical movement of the hand introduces a magical substance, and behold, pain, suffering are exorcised, the sense of misery disappears and the body is suffused with waves of pleasure.... All elatants poison sexual potency.... The pharmacogenic pleasure effect discharges the libidinal tension associated with these fantasies. The pharmacogenic pleasure process thus comes to replace the natural sexual executive.

In later writing, Rado deemphasized the replacement of sexual pleasure by pharmacothymic pleasure and placed more stress on the adaptive aspects of addiction.

Schilder believes that alcoholism arises from insecurity developed as a result of parental associations wherein the child is pushed deeper and deeper into an insecure emotional abyss by ridicule and passivity, by threat and corporal punishment, and by degradation. The child displaces the threats arising from the parents to the community at large, resulting in a heightened social tension and insecurity. Then in the adult, alcohol lessens this painful social situation and generates feelings of social acceptability and security during inebriation. When the alcoholically induced mood disappears, the original feelings return with renewed vigor, thus creating the need to drink again. As a result of this social insufficiency, the alcoholic person cannot develop close relationships with other people. Consequently, he develops a love for his own body, similar to what he wishes to receive from others—expecting special favors, appreciation, and love. Alcohol provides the feeling of being lovable and loved.

Others like Strecker and Lolli offer variations on this theme—a vulnerable individual rendered so by early life deprivation for whom alcohol provides magical relief from tension, depression, aloneness, hostility, and the myriad conflictual feelings that constantly plague the alcoholic person in a to and fro movement toward and away from alcohol. Crucial to all these theses is the implication of a specific characterological matrix of alcohol addiction.

Psychological theories are only partial answers since they do not weigh the physiological and sociocultural effects of alcohol use, nor do they explain why people with life experiences and emotional configurations similar to those they describe do not develop alcohol problems.

Learning theories. Learning theorists and conditioned reflex formulations have also made contributions to the thinking about alcoholism. The learning theorists, in general, would involve a drive setting responses into motion, responses that are also influenced by cues from other stimuli insufficient in strength to be drives. Whenever a response is unrewarded by a reaction that lessens the drive, the response tends to disappear, letting others appear. In other words, the extinction of successive nonrewarded responses pro-

duces so-called random behavior. When, however, a response is followed by a reward, the relation between cue and this response is strengthened. Consequently, in the presence of an identical drive and other cues, this response will be more likely to occur. This strengthening of the cue-response connection is the essence of learning.

Dollard and Miller pointed out that alcohol results in a temporary reduction of fear and conflict. It is the attempt to adapt to fear and conflict by alcohol, followed by the state of misery at its withdrawal, that produces the addiction cycle.

Shoben feels that readily available release from anxiety arising from the first drinking experience is the method by which reinforcement principles operate in alcoholism. The Skinner school of conditioning follows similar lines of reasoning: The diminution of anxiety by alcohol, practiced repetitively, becomes highly overlearned. Since the relief from anxiety is rapid in contrast to other learned patterns, a conditioned reflex—drinking—becomes preeminent over other behavioral responses, becoming nonadaptive and in time perpetuating the anxiety to which it was a response.

The classical studies of Masserman and Yum show that in the normal or preneurotic cat, alcohol resulted in excitement and exaggerated movements, disintegration of conditioned responses, and the display of fewer complex or more recently learned responses. As the effects of varying doses of alcohol disappeared, prior learned responses returned by stages. In neurotic cats alleviation of neurotic behavior was observed with alcohol (later learned neurotic patterns disintegrated). Therefore, alcohol produced in neurotic cats the same primitive goal-directed responses as in the normal cats, and, as the effect waned, neurotic reactions reappeared.

When offered milk, other fluids, and alcohol, neurotic cats chose alcohol more often than the normal cats did. With the receding of the neurotic patterns, however, their desire for alcohol abated. With the reintroduction of stimuli that produced neurotic behavior in the cats, preference for alcohol again occurred. Masserman and Yum concluded that the organism had to satisfy a need before "behavior directed toward its recurrent satiation became adaptively patterned."

The fact that alcohol pharmacologically is a cortical depressant which offers a blurring of anxiety-creating apperceptions and can provide prolonged tension release can result in addiction. Masserman later went on to write:

It is impossible to state the effects of any drug on any organism without considering the latter's genetic characteristics, past experiences and biological status, and its perceptions about motivations toward and evaluations of its current physical and social milieu. Clinical considerations indicate that these qualifications and contingencies as to all pharmacological action apply particularly to the problems of alcoholism in humans.

Conger tested his assumption that the Masserman-Yum observations represented simply an approach-avoidance conflict and that alcohol directly reduces the fear that motivates avoidance. Conger showed in albino rats that the alcoholized subjects resolved the conflict of approaching food and being shocked, whereas the nonalcoholized avoided the food-shock end of the experimental alley. Conger further showed that the resolution of the conflict is a result of the reduction in fear rather than a heightening of the hunger approach. He concluded that alcohol diminished the learned drive for fear-motivated avoidance. Furthermore, Conger feels that alcohol tends to decrease the strength of learned drives by leaving primary drives essentially unaffected. The differential reduction of fear is the crucial reinforcement that makes the learning of the drinking response so efficient in the alcoholic person.

Heilizer extended Conger's theory of approach-avoidance conflict in alcohol use. He discussed alcohol and its similarity to food and contended that "Food becomes a goal when the unpleasant sensations specifically associated with hunger occur; alcohol becomes a goal when unpleasant sensations of almost any variety occur." At the risk of simplifying a complex conflictual model concerning drinking behavior, Heilizer emphasized alcohol use *not* for its effect but because alcohol itself is "intrinsically positively valenced." Therefore, alcohol is used in approach rather than avoidance as Conger contended.

The animal studies reported on here and others under way offer meaningful information for understanding the development of alcoholism. What they cannot provide, as is the case with the psychological theoreticians, is the answer to *why* in certain drinking cultures alcohol is fitted into psychological, learned, or conditioned responses and results in alcoholism while in other drinking cultures it is not.

Physiological theories. In examining physiological components in the etiology of alcoholism, one is not here discussing either the physiological derangements of acute alcoholic intoxication, the metabolic and nutritional deficits of chronic alcoholism, or the well described physiological aberrations resulting from abrupt withdrawal of alcohol after prolonged, copious use. Of concern here are those theories that pertain to physiological factors creating and maintaining the addictive cycle.

Nutritional deficiencies have been incriminated as important links in the alcoholism chain. Westerfield reported that a restricted food intake of rats resulted in a marked increment in the voluntary intake of alcohol, and Mardones isolated a deficiency of vitamin B as increasing the intake of alcohol by rats. To Mardones this finding confirmed the genetotropic theory of Williams as to the etiology of alcoholism.

Williams formulated his theory because rats deprived of B vitamins select a solution of alcohol in preference to water. He holds that genetically determined and enzymatic defects impair the metabolism of

carbohydrates, rendering them ineffective as a source of rapid energy. Alcohol, serving as a replacement source, is craved primarily for this effect. Williams goes further and tries to relate this genetotropic theory to differences in cultural incidences of alcoholism by attributing them to hereditary differences in the intactness of metabolic mechanisms for metabolizing carbohydrates. What he does not demonstrate or explain is the apparent change in cultural incidence levels of alcoholism in acculturation phenomena. Williams believes that abundant satisfaction of every nutritional need abolishes the appetite for alcohol. He further contends that consistently good nutrition from childhood on seems to lessen the likelihood of the development of alcoholism. People who become alcoholic at an early age are those, according to Williams, with unusually high requirements for specific food factors, and their deficiencies reveal themselves earlier. The apparent increase in alcoholism is related to refined foods, contributing to physiological perversion.

Popham, Wexburg, Lester, and Greenberg have strongly criticized the theories and findings of Williams. The last two showed that, by introducing a third fluid choice (sucrose solution) under the same experimental conditions, the rats took the sucrose and not the alcohol. They further emphasized that, though the intake of alcohol by rats is high in some experimental situations, rats tend to space their drinks and thereby avoid intoxication.

Himwich regards alcoholism as arising from structural physiological aberrations wherein body and brain cells function more effectively in the presence of alcohol.

Smith contends that alcoholism is a genetically transmitted metabolic defect of the adrenal glands, heavily clustered among Celtic and Scandinavian people, whereby the adrenals are more susceptible to alcohol. Wexburg has carefully reviewed Smith's work and convincingly contends that adrenogonadal hypofunction is a complication—not a cause—of alcoholism.

Other physiological theories have been advanced: the masked allergy to alcohol of Randolph; the increase of anxiety, tension, and resentment factors in the blood of alcoholic persons reported by Fleetwood and Diethelm; thyroid deficiencies; and toxic products of alcohol metabolism producing direct addicting effects on the cortex.

The wide gamut of physiological theories merely reflects the difficulties of finding single cause modalities for highly complex behavioral disorders and the inherent difficulty of extrapolating from the controlled experiments of animals to the speculative conclusions concerning alcoholism in humans. What physiological findings do show us is, like the psychological evidence, that it is the effect of alcohol that is sought by the alcoholic person rather than the fulfillment of a structural deficiency state.

Sociological theories. Sociologists have made important contributions to the understanding of the

etiology of alcoholism. Horton studied 77 cultures' consumption of alcohol, subsistence security, and accessibility of alcohol. He demonstrated convincingly the high degree of correlation between subsistence insecurity and insobriety. In those societies where ceremonial drinking proceeds to states of unconsciousness, sexual and aggressive impulses emerge during the drinking bout. Horton believes that alcohol has the property of reducing anxiety and that its use is differentially determined, depending on the society's basic security and anxiety as well as the availability of alcohol.

Bales relates social organization and cultural practice to alcoholism based on: "(1) The degree to which the culture operates to bring about acute needs for adjustment, or inner tensions, in its members. (2) The set of attitudes toward drinking which the culture produces in its members. . . (3) The degree to which the culture provides suitable substitutive means of satisfaction." Bales has applied his thesis to an examination of a number of cultures and finds correlations of incidence of alcoholism with his formulations.

Snyder in his systematic study of Jewish drinking patterns and Barnett in his examination of New York's Chinese reveal the anti-alcoholic potential of ritualization of alcohol use, the abhorrence of intoxication, and minority status impelling the maintaining of control and the avoidance of scandal.

Gordon, in his desire to create an epidemiological climate for alcoholism work, has proposed that *any* use of alcohol is alcoholism, with addictive processes merely the end point of the total disease continuum. Gordon used the wide range model of diphtheritic infections: no infection, inapparent infection, atypical diphtheria, typical diphtheritic, and black diphtheria (abstainers, social drinkers, symptomatic drinkers, alcohol addict, and alcoholic deterioration and psychosis). Gordon's approach and formulation along public health lines offers a potential not only for reasonable epidemiological investigation but for preventive intervention.

Many other studies of a sociological nature could be reviewed and quoted. There is no single summary formulation, beyond stating that cultural determinants are of decisive significance in alcoholism. Most important for the future is the implication that cultural attitudes toward alcohol affect the individual early in his life development, and the role alcohol will play in an individual's psychological state has been set long before he takes his first drink.

Treatment

Treatment of alcohol problems results in a number of difficulties—none innately involved with alcoholism—usually the result of the attitudes of the care-takers. Acute intoxication is an excellent illustration. No one can deny that acute intoxication is a physiological disturbance in a response to too much of a drug. In no other part of medicine is the patient denied treatment

for his ills (even though, old-fashionedly, they are considered self-induced), except for alcoholic intoxication. Many a good hospital and many a good physician have turned the acutely intoxicated patient away without examination or help. These institutions or physicians would agree that intoxication from any cause is an illness, but their operational response is discriminatory and destructive.

The extent of alcoholic intoxication, however, is so common among nonalcoholic as well as alcoholic populations that more and more leaders in the alcohol field are pleading for units wherein individuals may receive the proper treatment for an intoxicating experience. Not only would these units offer the opportunity for good treatment for a common upset, but they would yield two other dividends: (1) an opportunity for early case finding and (2) the creation of an understanding climate toward alcohol use and its complications. Non-punitive and nonmoralistic attitudes toward alcoholism and early case finding may provide sufficient impetus for progressive programs in alcohol problems.

If the toxic state in acute alcoholic intoxication is not too profound, the patient may be treated with 10 to 25 mg. of chlordiazepoxide (Librium) four times a day for 1 to 3 days without hospitalization. Where the patient remains under the scrutiny of hospital personnel for a few hours, chlorpromazine (Thorazine) or other phenothiazines may be used in doses of 10 to 25 mg. daily for 1 to 3 days.

Whenever the intoxication is severe enough to require hospitalization, the patient may be placed on a regimen of 8 to 12 cc. of paraldehyde for the first dose, gradually reducing the medication by 2 cc. every 6 hours. Paraldehyde, when combined with 25 to 30 mg. of chlorpromazine four times a day, is useful in detoxifying severely intoxicated persons. Many therapists decry the continued use of paraldehyde because of their fear that it may lead to a substitute addiction, but this has not been the writer's experience with the combined medications. Others recommend chloral hydrate in doses of 1 to 2 grains at bedtime or barbiturates for sleep, but some find this less satisfactory since there is a potential for convulsions and addiction here without the medical benefit.

The state of dehydration should be determined, and fluids should be provided orally or parenterally; 1,000 cc. of 10 per cent glucose in distilled water or 1,000 cc. of 5 per cent glucose in normal sodium chloride solution fortified with 5 cc. of vitamin B complex is effective intravenously. If the patient is unable to tolerate medication by mouth, intramuscular injection of 50 to 100 mg. of chlordiazepoxide two to four times within 24 hours or chlorpromazine in similar doses may be used instead of the paraldehyde-chlorpromazine combination if the patient shows extremes of agitation and hypermotor excitement. Thiamine hydrochloride in 200-mg. daily doses may be given intramuscularly or by mouth. When convulsions are suspected, diphenylhydantoin sodium (Dilantin) in 1½-grain doses may

be administered orally three times a day. Where indicated, 15 mg. of propantheline bromide (Pro-Banthine) in an antacid four times a day may be given, and 4 cc. of Berocca-C 500 a day for 4 days parenterally may be administered. Where complications are present—such as tuberculosis, atypical pneumonia, subarachnoid hemorrhages, pancreatitis, liver disease—specific treatment measures must be introduced.

It is believed that the proper treatment of the acute phase may have important implications for the ensuing treatment of chronic alcoholism problems. Chafetz and his associates and others have shown that motivations for rehabilitative efforts may be enhanced by the proper initial therapeutic contact. Some workers contend that the ultimate battle may be won or lost at the time of the initial contact.

There are many treatments of alcoholism. That there are many forms of treatment does not mean that treatment is ineffective but merely indicates the wide diversity of problems that have to be dealt with in the proper treatment of alcoholism. A cardinal rule of therapy, however, is that the treatment program must be tailored to the needs and resources of the individual. Some workers contend that an agency or a care-taker may have a certain treatment program for alcoholics, and, when this one approach fails, the patient is considered a failure, hopeless, and untreatable. The question of the suitability of the prescribed treatment for the needs and resources of the patient is infrequently asked.

A second cardinal rule of treatment is to remember the chronicity inherent in alcohol problems. Too often the evaluation of alcoholism treatment is based on the criterion of abstinence—permanent and everlasting. In all chronic conditions, relapses are the rule rather than the exception. The horror felt at this understandable occurrence in alcoholism frustrates and infuriates therapists and creates in patients feelings of guilt, failure, and hopelessness. Abstinence is not the only criterion for successful treatment. Family adjustment, occupational effectiveness, social adequacy, and intrapersonal contentment along with post-treatment reduction of drinking behavior may be more effective than merely imposing total abstinence on the patient, with the result that he remains miserable and nonfunctioning. The careful evaluation of treatment effectiveness must take into account the development of alternative symptoms emerging during periods of abstinence.

Whatever the treatment mode, more and more evidence indicates that the most important ingredient is the relationship of the patient with another person or group. Whether it be clinic, group, physician, psychiatrist, social worker, drug, hospital, or Alcoholics Anonymous, there must be a positive tie between patient and treatment setting. The sooner the positive relationship takes place, the greater potential for a successful encounter.

A variety of substitution therapies—vitamins, hormones, carbohydrates, tranquilizers, sedatives, drugs—

have been employed in alcoholism, but none appear to achieve a success rate above that seen with placebos, and all suggest psychotherapy as an adjunct to treatment. Where there is a recognizable deficit, proper implementation must be made, and where the therapist feels, as a result of his evaluation of the patient, that a tangible proof of his interest in the patient is essential, the prescription of medication is important.

Physiological treatment. Two physiological forms of treatment are worthy of mention: aversion therapy and disulfiram (Antabuse) therapy.

Aversion therapy. This form of treatment uses emetine or apomorphine in an attempt to create a distaste for alcohol by developing a reflex association between alcohol and vomiting. The hypothesis holds that the repeated association between alcohol and illness induced under appropriate conditions can produce a conditional response to the drinking of alcohol. Alcohol must be drunk slightly before the onset of the drug induces nausea and vomiting to introduce true conditioning, according to Voegtlin. Conditioning sessions, using the patient's favorite type of beverage, last for 30 to 60 minutes and are given on alternate days for a total of four to six treatments. Reinforcement to aversion by one or two reconditioning experiences is given any time a patient develops a desire to drink. At the end of 6 months, reconditioning experiences are administered.

Most therapists employing aversion therapy agree that there is a higher improvement rate among patients who have had a sustained relationship with the therapist before or after treatment and who are in the higher socioeconomic groups. There is also an automatic selection factor in patients agreeing to undergo this treatment voluntarily.

Disulfiram therapy. This treatment was introduced in Denmark in 1948 and swept with high hope into most treatment centers in the world. Enthusiasm has diminished more recently, but it is still an important drug in alcoholism. Disulfiram (Antabuse) is important because patients who are taking the drug have an abnormal reaction to alcohol; five to ten minutes after the ingestion of alcohol, the individual on disulfiram develops a sensation of heat in the face along with intense lobster red flushing of face, sclerae, upper limbs and chest. Along with heightened coloration, the disulfiram reactor suffers constriction in the neck, irritation of the trachea, spasms of coughing, and labored breathing. The most intense symptoms develop 30 minutes after the ingestion of alcohol. People who have consumed large amounts of alcohol become nauseous, and the flushing is replaced by pallor due to a considerable hypotension. Vomiting begins, and a feeling of uneasiness and apprehension develops, which most people find the most disagreeable symptom. The initial dose of disulfiram is 0.5 gm. once daily for 1 to 3 weeks.

Disulfiram alters the metabolism of alcohol so that a toxic product, acetaldehyde, is formed. Because di-

sulfiram is slowly metabolized, patients may be maintained on daily doses of 0.25 to 0.5 gm. and must be without alcohol for 4 days after the last dose. Alcohol in any form must be avoided while taking the drug. Most workers feel it is an adjunct to treatment and offers the greatest potential for delaying impulsive drinking episodes. Usdin et al. feel that the psychological significance of disulfiram may be as important as the pharmacological, and its effectiveness may be related to the strength of the doctor-patient relationship.

Psychological treatment. The broad range of psychological therapies have been the most uniformly advocated in alcoholism, although there is no uniformity of opinion as to which type of psychological treatment is most effective. Group and individual psychotherapy, milieu therapy, family therapy, casework, and so forth have been used in alcoholism.

Psychotherapy. As intimated earlier, the initial contact with alcoholic persons is crucial to successful treatment. In the early encounter, therapists need to be active and supportive because patients with alcohol problems anticipate rejection (and interpret the passive role of a therapist as rejecting) and are depressed. The therapist must also deal with alcohol as a psychological defense: the pharmacological effect of alcohol allows the formation of an emotional and intellectual barrier between patient and therapist, and therapeutic efforts are blunted. The lack of this barrier should not be held out as a precondition for therapy, but its removal should be an early goal for effective progress.

The goals of therapy must be consistent with the resources of the patient and his environment and should be based on an evaluation of the individual. They will vary from one person to another.

Denial, a major mental mechanism in alcoholism, must be dealt with as soon and as often as it becomes recognizable. Therapists must guard against their own unconscious denial mechanisms fitting into those of the patient. Hostility toward drinking or alcoholic persons by the therapist will easily be noted by the patient and will be used as a counter-therapeutic force. Therapists must be prepared to have the therapeutic bond tested again and again and cannot hide behind the screen of the patient's lack of motivation when relapses become threatening to the therapist and not a part of his understanding of the therapeutic process.

Depressions can be countered by the active, supportive role of the therapist, as already noted, and at times by the addition of antidepressant drug medication where necessary.

Regardless of the therapeutic modality employed, sophisticated therapists view the problem not in terms of an isolated individual but in terms of the dynamics of an individual who is part of a social system. This often includes treating members of a family or a marriage partner, recognizing forces in the environment that operate in a negative therapeutic manner. Ther-

apists dealing with alcohol problems cannot use rigid approaches but must be daring and inventive with each patient and circumstance.

Alcoholics Anonymous. This loosely organized voluntary fellowship of alcoholic persons is a well known organization of self-help available to alcoholic patients. Its goal is sobriety, and its greatest impact has been in pointing out to noninterested professionals that alcoholic persons can be helped. Alcoholics Anonymous waged the fight and furnished the interest when others hid behind moralism and pessimism. It imparts comradeship, since all members suffer the same disturbance; it encourages introspection and confession of a superficial nature; it gratifies dependency needs via group identification or by caring for new intoxicated members; and switching from alcohol to Alcoholics Anonymous offers a less destructive social outlet for addictive needs. One could say much for or in opposition to Alcoholics Anonymous, but some feel strongly that its role has been and is important.

Chapter 28

Personality Disorders. IV: Gross Stress Reaction

28.1 GROSS STRESS REACTION. I

ROBERT J. WEISS, M.D.

HENRY E. PAYSON, M.D.

Gross stress is any unusual influence or force perceived as threatening a vital goal or need of an individual or group. In its severest form, it brings about an insoluble conflict of vital goals or needs. Since an individual's group identity is an important influence on his adaptive capacity, group interaction and identity play important roles in both individual and group reactions to stress.

Stress reactions are attempts to defend or reconstitute the personality or group from disorganization. The disorganization that results from unsuccessful reactions can precipitate or extend preexisting neurotic and psychotic maladaptation. Stress reactions can break down preexisting healthy adjustments and patterns of behavior, or they may enable an individual to advance to a healthier level of adaptation. Successful or unsuccessful reactions to stress are dependent on personality development and social structure. For example, serious physical illness or community disaster is associated with the widest variation of reaction patterns. One cannot predict with certainty a specific reaction of any individual or group unless a great deal is known about the predisposing personalities and the immediate social organization. Individuals and groups are known to sustain severe stress—such as isolation, death of loved ones, and serious property loss—without breakdown of adaptive capacities, even when it is impossible to repair or replace the damage or loss. Similarly, there are frequent examples of total disintegration of adaptive capacities in the face of relatively minor stresses. These failures most often occur when the task is essential to a vital goal or need of the individual or group and when the successful performance

of the task would put the individual or group in conflict with other vital goals or needs. The most frequently cited example of such breakdown is the disorganization of a soldier in the face of the conflicting needs to avoid danger to self and to be honorably accepted by members of his peer group.

Incidence

There can be no epidemiology of psychological stresses, but rough correlations can be found between stress reactions and subcultures and between social structures and prevalences of certain types of psychological disability. For example, amok or running amok—which has been described in Malaya, the Philippines, parts of Africa, and the old Viking civilization—and latak—also described in Malaya, the Philippines, parts of Africa, and South America—seem to be two functional psychiatric syndromes rarely seen in Europe or the United States that are known to be precipitated by circumstances of acute stress. Catatonic schizophrenic patients in remission very often, and sometimes reliably, develop catatonic schizophrenic symptoms in circumstances of acute stress. The reaction to stress also depends on the age and the physiological integrity of the individual or of key individuals in groups. Inadequate nutrition, infection, exposure, incapacitating injury, and poor physical preparation are well known as predisposing to untoward adjustments to stress.

Clinical Description

Both favorable and unfavorable reactions to stress appear to take place in somewhat comparable but overlapping phases. In each phase, there is interaction between the stress and the adaptive capacities of the group or individual. Four overlapping phases have been reported in stress reactions: (1) the anticipatory or threat phase, (2) the impact phase, (3) the recoil phase, and (4) the post-traumatic phase. The second and third can extend from minutes to many hours. The first and the last may persist for the duration of life.

Anticipatory or threat phase. Most people live without a sense of imminent danger. They assume an illusion of invulnerability in which it is almost always felt that whatever is going to happen that may be bad is not going to happen to *them*. At times, the illusion has the useful function of protecting the individual from limiting his life or from living in a constant state of terror in relation to the real dangers that life holds.

Excessive awareness of a threatening danger may turn the anticipatory phase itself into a prolonged impact phase. This can contribute to progressive disorganization and maladaptation in the face of ever present situations that are potentially stressful. Maladaptations that may result are phobic, self-punishing or expiatory reactions. The excessive awareness is caused by displacement of anxiety from guilt associated with other problems to the anticipated danger. The sufferer seems to wallow in and sustain prolonged worry, with attendant maladaptive behavior.

Many individuals use only the minimal degrees of denial necessary to prevent panic and allow some preoccupation with the future and the threatening danger or stress. A certain amount of "worry-work" is then possible; the individual or group attempts to assess the threat or danger and makes an explicit inventory of all efforts, strengths, alliances, and supports it can use to meet the threat or danger. This results in such adaptive activity as training and drills to meet the anticipated stress. The training may be real or in fantasy. The degree to which the individual allows the reality of the threat to enter conscious awareness determines the reality investment in the training. Historical accounts of disasters at sea often make reference to the different individual attention paid to routine life boat drills required on all ships. At the time of a disaster, some individuals are unable to remember where their life jackets are; others find their jackets with ease and quietly go to their boat station. The previous training of the crew in such drills and the degree of discipline instilled can make the difference between saving the majority of people involved and tragic mass loss of life. A well trained crew responds automatically to commands. This brings about immediate communication and structuring in the midst of severe stress. The resort to an automatic response which every soldier is trained when his rifle jams—pulling back and releasing the bolt of his rifle—is done so quickly that it is observed to take place reliably during a heavy fire fight that otherwise might have become a disaster if more than a few rifles had jammed.

Admission of both mother and patient to the hospital a day or so in advance of tonsillectomy, the open and anxiety-free discussion of the anesthetic induction and the immediate postoperative pain, and the practiced breathing through the mask with the anesthesiologist before induction are all procedures that promote necessary worry-work prior to the facing of the trauma.

"If I do get picked to go overseas, I wonder how I'll behave," and "If *my* child were to get cancer like hers did, how would I control myself?" are familiar examples of individual worry-work with which the individual prepares in fantasy. Excessive denial or unawareness of danger deprives the individual or group of moderate worry-work and can result in overwhelming shock during the impact phase, followed by permanent psychological incapacity. Even when there are warnings of national disasters, many citizens do not prepare themselves for the disaster; they maintain a posture of denial and an illusion of invulnerability. People questioned following large disasters such as tornadoes, floods, or earthquakes have responded by saying, "I thought it was going to hit the other side of town" or "I didn't know that this area was flooded." During the bombings of London in World War II, there was no mass exodus from the city, and it was found that only a small percentage of the population were fearful and anticipated the dangers as threatening to themselves. During World War II, when air raid drills were held regularly in the New York City school system, most children took this as a matter of course and did not become upset or unduly concerned with the possibility of danger. This was true also when there were air raid practices for the city as a whole.

A small percentage of the population becomes frightened and phobic about the dangers presented and sometimes utilize magical constructs and the mechanism of "undoing." An example of this was seen during the extensive bombings of England in World War II. In some communities that had been under intensive nightly bombing, it was considered taboo to talk about the fact that the siren had not sounded yet that night or to make comments that would indicate an awareness of the lack of an air raid at that time. Magical undoing is common in stressful situations in society and not restricted to times of mass threats. Major league baseball players during a pennant drive frequently practice superstitious rituals to the amusement of the onlooker. The kind of extreme denial and illusion of invulnerability frequently seen in surgical patients is one of the major factors in the development of severe post-traumatic neurotic reactions.

Total denial of threat or disaster sometimes extends through the period of impact, even to the extent of allowing an individual to deny his own need for medical care. Wolfenstein reported the reaction of a bus driver whose bus was overturned by wind during a tornado. He felt impelled to take care of his injured passengers, despite the fact that he himself had a large portion of his thumb almost severed and hanging by a thread of flesh. The bus driver reported that his only concern was that the piece of his thumb got in the way as he tried to help his passengers and get them to the hospital. He had tried, unsuccessfully, to bite off the hanging portion of his

thumb "because it was in the way." It was not until after he had gotten all his injured passengers into the hospital and arranged for their care that he admitted his own injury, fainted, and had to be carried to the treatment area to have his injury dealt with realistically.

The anticipatory phase in which there is tolerable but sufficient worry-work is an essential preliminary to successful adjustment to psychological stress. The focus of attention is on the future.

Impact phase. During this phase, variable degrees of personality or group disintegration may occur, even in the previously well adjusted individual or group. The focus of attention is on the immediate present, and the phase lasts for the duration of the stress. Physiological reactions to immediate trauma include vasomotor response, increased secretion of epinephrine and norepinephrine, dilated pupils, increased muscular tension, gluconeogenesis, and anti-diuretic hormone and adrenocortical steroid hormone release. Neurophysiological changes may include an initial increase in alertness and a broadened attention and memory span. If the stress is overwhelming in intensity, there follows a state of decreased alertness, numbness, dulling of sensorium, narrowed attention span, obliteration of memory function, disorganization of thought content, and suspension of affective awareness. Behavior rapidly becomes automatic and in many regards tends to be conditioned by contemplated or practiced reactions to the stress that took place during the anticipatory period. There can also be a repetition of learned behavior that an individual has used in other anticipatory or impact phases.

Tyhurst has noted that 12 to 25 per cent of people in this phase are "cool and collected." One of the major devices used by this group is keeping busy with anticipated or semiautomatic behavior and helping in some way to alleviate the distress of others. It is well known that the reaction to stress can be contained and directed if there is effective leadership that organizes the group into some kind of purposeful activity and thus permits their organizational or adaptive capacities to reduce the anxiety. In situations where it is not possible to indulge in purposeful activity and where there is no leadership, panic sometimes ensues. An example of this is reported to have occurred during the Japanese bombings of Chungking, China, when there were adequate and excellent caves to shelter the entire population. The people in the caves sometimes panicked and rioted, resulting in many more injuries than resulted from the bombings themselves.

Tyhurst stated that 75 per cent of most populations react at least initially by being stunned and bewildered. Both the cool and collected and the stunned and bewildered groups gradually, if not immediately, seem to immerse themselves in activity, such as walking,

reporting, and contacting others, particularly relatives and friends.

During the impact phase, an unknown percentage of individuals lose consciousness either through syncope attacks or else by undergoing complete dissociative amnesia for events that occur during the period of trauma and part of the period of recoil. These individuals are often described as losing consciousness, even though they may have actually had a dissociative or fugue state.

Ten to 25 per cent of the population show inappropriate responses, severe confusion, or total loss of control of motor behavior. The result of these responses can range from extremely destructive or haphazard aggression to grossly inappropriate, automatic, or stereotypic behavior and catalepsy. Some individuals show severe anxiety. During the traumatic and recoil periods, the recall of behavior by this 10 to 25 per cent is variable. It seems likely that the impaired recall serves to enable the individual to relinquish responsibility for unacceptable behavior or experiences, such as trampling and assaulting.

Recoil phase. During the recoil phase, emotional expression, self-awareness, immediate memory processes, and behavioral controls begin to return but are not complete. There may still be a limited perspective and continued compulsive seeking for dependency attachments. These are manifestations of beginning reintegration of adaptive function impaired during the impact phase. These restitutions and personality reorganizations and the supportive intervention by others are of critical importance to subsequent psychological events.

There are numerous reports of individuals whose usual reaction patterns have been grossly shattered during the impact and recoil phases. Unusual adaptive responses that call on resources the individual was unaware of possessing may result in a lasting increase in self-esteem and an increased capacity for adaptive behavior in the face of life stress. The recall of acts at this time, if conforming to ideals shared by one's peer group, seem to promote some personal and group reintegration on a level that may be more secure and confident than that which existed prior to the stress. One can refer to the obvious pride and confidence shown by a child who has faced a surgical procedure "like a little man" or the obvious generation of high morale and *esprit* of a well led combat team after its success in combat.

Certain educational programs—notably, the Outward Bound Movement—deliberately confront teenagers with psychological stress in controlled situations after an appropriate anticipatory preparation. Group support and expert leadership combine to bring about an increased sense of self-confidence and group interdependence, which results in a higher level of individual adaptive capacity.

Conversely, an awareness of maladaptive behavior in difficult circumstances during the period of

recoil can result in a damaged self-image, a shattering of individual self-confidence or of group morale. This can cause permanent impairment of all subsequent performance, even in the face of minor stress. Military units have had to be broken up and the men assigned to other units after a defeat that was followed by maladaptive behavior.

Post-traumatic phase. This begins when the sense of self has been maximally reconstituted. Orientation, motor function, and affective control are re-established. At this time a more or less fixed, although specially modified, recall of the stress at the time of impact is brought to consciousness. The full awareness of the trauma is to some extent socialized by group or individual support received (or missed) during the recoil phase. Successful stress reactions during this phase involve personality or group assimilation and sharing of the emotionally charged experiences with others, such as having several good cries. Recovery seems to be spontaneous, with the intensity of emotional experience gradually waning. Frequently, very intense group loyalties and an added sense of group identity and individual self-confidence begin at this time.

Unsuccessful post-traumatic reactions seem to be characterized by permanently altered and often unfavorable concepts of the self, the group, and the outer world. Consequences of these altered concepts are chronic anxiety, depressive and fatigue states, recurrent catastrophic dreams, guilt, anger, and aggression.

Many individuals who have survived an overwhelming major disaster share in common a severe guilt for surviving and in different ways express the unconscious thought, "Others I saw dying were doing so in order for me to live." Such guilt may be displaced from pre-existing psychological problems and may be dissipated in phobic elaboration, defensive ceremonials, tics, and rigid obsessional constriction of interpersonal relationships. Sometimes, as in the Hiroshima atomic bomb disaster, there is an experienced death symbolism of individuals who regard themselves as living dead: "I almost died; I should have died; I'm dead." Such repetitious experience has been interpreted as an unconscious obeisance to and propitiation of the dead in order to be allowed to remain alive. A similar clinical picture has been described in survivors of Nazi concentration camps.

Anger and aggression are often observed in severe post-traumatic reactions, and these emotions frequently elaborate into chronic depression, chronic paranoid states, or a proclivity to explosive social aggression. Sometimes recurrent syncope, dissociation, fugue states, or amnesia occur in company with explosively aggressive behavior. The last three may be conjectured as possible waking states that are analogous to the recurrent catastrophic dream states in which trauma is painfully reexperienced.

Prevention

The best prevention of an adverse stress reaction is to ensure an adequately supported anticipatory phase or to lessen the intensity of the sudden onset of the impact phase. For example, the thorough psychological and physical preparation for an anticipated hurricane with adequate warning of the approaching storm reduces the incidence of adverse stress reactions.

An individual who is about to undergo a major surgical procedure should be allowed to establish a secure relation with the anesthetist and surgeon in the anticipatory stage. Not only should he be well informed of the trauma and care procedures he is about to receive, but he should be allowed to express and share with his doctors and relatives his anxieties and special emotions that are evoked by the anticipated threat. Most postoperative psychoses are observed when there is little or no understanding relationship with the doctor and poor relationships with members of the immediate family.

The trauma or stress itself can often be lessened or eliminated by attentive clinical care, which often involves the use of respectable amounts of morphine, barbiturates, or ataractic drugs. Patients are sometimes psychologically invalidated by finding themselves isolated and abandoned during the impact and recoil phases of a crisis due to illness.

Physicians who are reluctant to share with their patients awareness of a terminal or incurable illness often rationalize their attitude with: "In my experience, to tell a patient he has cancer deprives him of hope and inevitably leads to a severe depression and withdrawal." Actually, the doctors are afraid to relinquish the role of omnipotent healer. They frequently resort to the stratagem of a pseudodiagnosis, with which both patient and doctor can maintain an illusion of curability; for example, the patient with lymphoma is told he is being treated for an infection or anemia. Occasionally, when forced by patient or circumstances to reveal the true illness, danger, or stress, these physicians become so anxious that they react in inappropriate ways, one of the worst being abandonment of the patient. The depressions the doctors fear are traumatic, indeed, but they are the result of preventable gross stress reactions, not the result of impending loss or death.

Treatment

The aim of treatment of untoward stress reactions is identical to that of the stress reaction itself: to protect or reconstitute the personality or group from disorganization. The method of treatment is to introduce effective leadership and control as early as possible in the recoil or post-traumatic phase so as to allow the personality or the group to complete an assimilation of the affective qualities of the impact and recoil experiences as soon as possible. Leadership

has qualities and intensity of intervention that are different for each of these two phases.

In the recoil phase. Since this is a time of group disorganization or self-disorganization, *directive* leadership is indicated. Generally this entails presentation by the leader of himself as a model of alertness, self-discipline, and reduced anxiety. The disaster worker, combat leader, police officer, or doctor who is able to do this has already achieved a position from which his directions are acceptable. His technique of control of individuals or groups is to give simple matter of fact directions primarily to establish means of reliable communication between himself and the victims; to identify the adequately functioning parts of the personality or of the group for support in carrying out the direction and control; to assess the possibilities of still present danger; and to direct the more automatically controlled functions or functionaries to assist in evacuating survivors, providing first aid, making identifications, etc. The use of appropriate medication to help overcome acute panic and excruciating pain may abruptly terminate acute panic reactions and enable personality or group reintegration to begin at once.

In the post-traumatic phase. During this phase, adverse reactions are already indications of incomplete personality or group reintegration, and the personality or the group has already become maximally reconstituted; therefore, therapeutic leadership tends to be evocative, nondirective, and supportive. The aim is to enable the individual or the group to re-experience or abreact as soon as possible the affective experiences of the impact and recoil phase and to promote reliving and assimilation of the experiences. Again, the leader has to establish himself as a model of internal discipline, receptivity, and low anxiety. He encourages verbalization of the experience in a supportive environment, at the same time attempting to evoke from the victims whatever strengths and aspects of behavior tend to reconstitute the former self-esteem of the individual or group. For example, the soldier is allowed to abreact his combat experience to an empathetic and supportive doctor and is quickly returned to the scene of combat to enable him to act and behave in such a way as to regain his recently shattered self-esteem. At the same time, an individual who has been able to abreact and assimilate the affective experiences of the trauma carries, with the reassimilation, the experience of group acceptance and support.

As a general rule, the longer the time lapse between the impact phase and the time of treatment, the poorer the prognosis. In chronic reactions, one notices that the victim continues to struggle to recover through reliving the crisis. Esteem-building participation in a comparable crisis may be the only method to enable reconstitution of the original self-image, assuming that the setting of the crisis is adequately

anticipated and sufficiently supported. Contrived psychological stress in carefully controlled settings, such as with the use of certain psychotropic drugs, may be beneficial.

Suggested Cross References

Specific reactions to the stress of combat are discussed by Brill in the next section. Some of the unusual culturally determined reactions to stress, such as amok and latah, are further described by Lehmann in Section 32.1 on unusual psychiatric disorders and atypical psychoses in this area. Adjustment reactions to stress in childhood and adolescence are discussed in Sections 40.1 to 40.3, and the adjustment reactions of late life are discussed in Goldfarb's section on geriatric psychiatry (Section 47.1).

28.2 GROSS STRESS REACTION. II: TRAUMATIC WAR NEUROSIS

NORMAN Q. BRILL, M.D.

Since psychic equilibrium involves a balance between an individual's defenses and adjustment mechanisms and the stress to which he is exposed, it follows that any unusual stress or any gross increase in stress that disturbs a person's equilibrium is likely to result in some emotional, behavioral, or psychological abnormality, even in the individual who shows a normal adaptation during ordinary circumstances. This reaction may be transient or persistent. It may be any one of the known types of psychiatric disorders.

The term "*war neurosis*" is a catch-all phrase that is and was used for a wide variety of abnormal reac-

tions that occur in military personnel in wartime. In some instances the reaction is due to severe overwhelming stress, but in other instances the reaction is merely the persistent or continued manifestation of an emotional disorder that existed prior to the individual's entry into the service. Neither the American Psychiatric Association standard nomenclature nor the International Classification of Diseases includes the term "*war neurosis*." Such reactions are now classified under the term "gross stress reaction" when they are transient and clearly the result of an unusual, severe, or overwhelming military stress. When the reaction is unrelated to some severe objective stress, it is now properly classified under the appropriate type of psychiatric, psychosomatic, psychophysiological, or other type of reaction.

History

In World War I the term "shell shock" was applied to a wide variety of psychiatric disorders that developed in men in combat. Some were characterized primarily by gross conversion symptoms like paralysis, pseudoconfusion, or blindness; others were characterized by hypochondriacal, phobic, or anxiety symptoms, freezing, catatonic-like stupor, running amuck, irritability, overwhelming depression, startle reaction to noises, somatic symptoms, gross tremors, restlessness, insomnia, or nightmares or repetitive battle dreams. It was first believed that these various disorders resulted from concussive or other effects of the explosion of shells on the brain. It was not long, however, before the psychogenic nature of the condition was recognized and the term was dropped.

In World War II psychiatric disorders for which no diagnostic term existed made their appearance in large numbers of men in combat. In some instances, as in World War I, the outstanding symptom was confusion; in others, aimless flight, severe depression, irritability, paralysis, severe headache or other somatic symptoms, sleeplessness, anorexia, extreme hypersensitivity to noise, tremulousness, severe anxiety, panic, and startle reactions. In many instances, there was just the single complaint, "I just can't take it any more," or "I can't stand those shells," or "I just can't control myself any longer."

Grinker and Spiegel described and classified the varieties of regressive behavior seen in men in combat in their classic publication *Men Under Stress*. W. C. Menninger quoted a wartime broadcast Eric Sevareid made from London, which was later published in his book, *Not So Wild a Dream*. In it he vividly described some of these combat reactions.

The one [on a desolate airfield in the Gulf of Aden] who sat for three hours, unmindful of the crushing heat, his eyes fixed on a stone. He had been there eighteen months and he didn't talk to his comrades any more.... The soldier with a child's face, who stumbled from the exploding field near Anzio with not a mark on his body, but with his eyes too big, his hands senselessly twisting a towel, and his tongue darting in and

out between his teeth.... The young corporal with the radio post deep in the Burma Jungle... who rose suddenly from his bunk in the night and walked straight into the woods, walking westward.

There was great reluctance to apply diagnoses of psychoneurotic reactions or psychotic reactions (which seemed more appropriate in some), because their relationship to overwhelming stress rather than to early childhood experiences was so obvious. The man who broke down crying and could no longer function after all the men in his squad had been killed or wounded did not somehow fit into the traditional picture of the neurotic. In fact, there was a high incidence in normal men who were exposed to combat of neurotic and psychosomatic symptoms and reactions resembling those seen in neuropsychiatric casualties: nightmares, trembling, fainting spells, extreme nervousness, and upset stomachs. It seems clear that some were disabled by these symptoms and others were not.

Many men who broke down in combat improved dramatically after a few days' rest, sedation, hot food, recreation, relaxation, and sympathetic encouragement or a chance to blow off steam. Diagnoses of "combat fatigue" or "combat exhaustion" were invented for these conditions. In the Air Corps, the term "operational fatigue" was coined. It was only when these reactions did not clear up and persisted in the same or modified form that the traditional diagnoses of anxiety, depressive, conversion, psychophysiological, and psychotic reactions were entertained.

Etiology

The incidence of gross stress reactions was observed to bear a rather constant ratio to the number of men who were killed and wounded. It indicated that there was a clear cut relationship between the severity of stress—in this case real danger—and the chance of emotional breakdown. It was this that led to the conviction that every person had his breaking point, that there were limits to the amount of stress each person could tolerate. Since many of the men who broke down in combat had no discernible predisposition and had, as far as anyone could tell, been normal, well adjusted individuals prior to entering the service, it became clear that it was not just weaklings who developed emotional disorders. Some of the more understanding attitudes toward the mentally and emotionally ill that developed in the public after the war were probably related to this understanding.

Combat stresses. Combat was by far the most common stress that precipitated psychoneurotic breakdowns in World War II. The real threat to life was often associated with other severe stresses, such as lack of sleep, physical exhaustion, hunger, cold, loss of buddies, large number of casualties in one's outfit, wounds, injuries, and illness. It was difficult to tease out the exact contribution that each made. The

final stress that seemed to precipitate the breakdown was often the last of a long series of stresses that gradually wore the soldiers down to the breaking point.

How long a man was exposed to stress was crucial. If there was some end point, some relief that a man could look forward to and rely on, it made the stress more tolerable. The rotation system used for Air Force and Navy personnel, which provided for return to the United States after a specified number of combat missions or time spent overseas, undoubtedly prevented many breakdowns.

In some instances the reaction to stress was a delayed one and did not occur until after relief from combat or return to the United States from overseas. There were a considerable number of men who broke down when they were confronted with the prospect of discharge from the service and return to civilian life.

Noncombat stresses. Stresses other than combat also contributed to the high incidence of emotional breakdown in the service. Some men who were called into service had never before spent a night away from home. Others experienced economic hardship and sexual problems in the service. For others, being away from home and not being able to deal with domestic difficulties was stressful. A good deal of anxiety was produced in many merely on entering the service with all its unknowns, privations, and dangers. Homesickness, regimentation, deprivations, lack of physical comfort, change in diet, excessive physical demands, lack of sexual outlets, illness, extremes of climate, and fear of future combat were more stressful for some than others.

Some were given too much responsibility, others felt useless or frustrated because their talents were not fully exploited by the military. Some were unable to adapt to assignments for which they were not adequately trained; some were exposed to the demoralizing effect of poor leadership, lack of earned promotion or other recognition, inactivity, frequent transfers, isolation, and uncertainty about the future.

These noncombat stresses were described by W. C. Menninger in his monumental review of psychiatry in World War II:

Uncertainty, as to where and when and what, filled the mind of the average soldier after his unit received orders to move. It went with him through the staging area, onto the ship, during landing in some foreign country, and while awaiting the assignment to action. Rumors in the army were always rife, but the impending departure from the U. S. speeded and multiplied these a hundredfold. One can imagine the intense emotional feelings of the soldier at the time he was leaving his country, going to a place about which he could guess only perhaps from the nature of the clothing issued to him, facing the prospect of thousands of miles separating him from home for a long time, knowing that he would cross water, every mile of which might be infested with potential threats to life. All of these were stresses of no small moment. Stress was particularly conspicuous on a ship which was assumed to be heading for

an amphibious landing. No one knew whether the 'show' would start that day or the next or the next week. Of necessity, the men were cooped up in a small area with little or nothing to do but sit and think and wonder (although an attempt was made, where possible, to continue training aboard ship). Uncertainty became nigh unbearable through such waiting periods. Those necessary transitions sometimes lasted days and sometimes dragged into months during which no one seemed to know the why of the waiting, whether or not it was necessary, or what was to come after the wait.

Along with the uncertainty regarding the landing or possibility of combat was the uncertainty about other lurking dangers, particularly for soldiers, in the Pacific. A specific fear was of the unhealthy climate which carried with it strange tropical diseases. Every soldier became somewhat educated about malaria. He had to take atabrine as a preventive or suppressive measure. Even so, rumors developed that made this requirement more difficult to carry out. There was a widespread, groundless belief that the drug made one sexually impotent. Another rumor was that the drug made one crazy. Soldiers would hear of other new or strange diseases—hepatitis, filariasis, kala-azar, scrub typhus. Each would produce mild concern in the susceptible personality.

The constricted nature of the living area often imposed a further stress. There were literally hundreds of installations in which the soldier was limited to a small section even though on a large land area. This was also a problem when men were stationed at little outposts or on tiny islands. Leaves could not be granted for there was nowhere to go; there were minimal facilities for recreation; often there were no other white people. The effect of continued monotony, often coupled with terrific extremes of climate, uncertainty, separation from familiar surroundings and activities, and too much time for thinking, was always disastrous in its effect on morale.

In many studies, successful soldiers showed a much lower incidence of childhood neurotic traits, of unsatisfactory home situations, and of previous personality or mental disorder than did soldiers who developed psychiatric disabilities. In contrast, other researchers were impressed with the high incidence of family psychopathology, divorce, and unhappy childhoods in soldiers who, although exposed to severe stress, did not break down. It was common experience that many soldiers with apparently healthy backgrounds often became noneffective on short exposure to the stress of combat, and highly neurotic individuals often made successful soldiers.

Psychic factors. The psychic forces operating in the production of gross stress reactions varied from individual to individual. There were four significant forces in the development of the gross stress reactions of combat: mobilized aggression, depletion or loss of ego strength, loss of the ego supports in the form of leadership and group identification, and specific precipitating trauma. The ego's capacity to control the forces within the personality was decreased in varying degrees by the cumulative effect of unrelieved emotional stresses.

A state of helplessness, so often induced by the loss of a leader or separation from a buddy or the unit, tended to contribute to the development of neurotic reactions more often than had been realized at the beginning of World War II. Conflict between duty and self-preservation, complicated by the touching off of

unconscious earlier fears, played its role in the production of breakdowns.

In the face of severe stress, important factors tend to strengthen an individual's resistance to the stress: good motivation and identification with his unit or associates, good esprit de corps, fair discipline, fair rewards and punishments, the expectation of relief from the stress after some definitive time, adequate training, proper assignment, confidence in weapons or instruments, and the knowledge that creature comforts will be provided when possible. It was learned that the relatively simple technique of teaching soldiers that fear in the face of danger was normal and that fear could express itself by various bodily symptoms proved extremely helpful and reassuring to many men who had not known these things before and had assumed that they were ill if they felt afraid or had an experience of incontinence or trembling.

Predisposing factors. A study (Brill and Beebe) of the characteristics of men who broke down in service in World War II showed that they were a little older, a little more often married, and with less education than a comparable group of soldiers who did not break down. They did not differ, however, as to intelligence, civilian occupation, religion, or race. Those with family histories relatively free of psychiatric illness of any kind had a breakdown rate that was less than half of that seen in men with family histories of psychiatric disorders.

As might be expected, the preservice personality of the individual was the one variable that, in samples matched for military experience, played the greatest role in determining the chance of breakdown. The chance of breakdown for men with preexisting overt neuroses was seven or eight times that for the previously well integrated men. Those who were better adjusted in civilian life did better in general than those who had been maladjusted, whether it was in their families, school, work, or community.

It would be a mistake, however, to assume that all those who had some emotional difficulty prior to entering the service would break down. It was estimated by Brill and Beebe that, of those who served in the Army who would not have met the psychiatric criteria for entering the service had their conditions been known at induction, only one third broke down while in the service. It was not possible prospectively or retrospectively to determine who would comprise the one third that would break down. It was not possible to anticipate the stress to which each of these men would be exposed or to measure ahead of time the supporting factors they would experience.

There was a tendency to underestimate the adaptive capacities of neurotic soldiers and insufficient recognition of the pertinence of the specific nature of the stress. It was proved repeatedly that predisposed individuals were in many instances able to endure the most strenuous combat experience without decompensating.

Furthermore, psychiatric evaluation of an individual does not necessarily measure the ability of the individual to function in a group. The importance and strength of powerful compensating mechanisms was not appreciated when "off-the-cuff" opinions of suitability for admission to the service or for particular assignments were made by psychiatrists or other medical examiners on the basis of fragmentary data.

Treatment

A lesson that had been learned in World War I had to be relearned in World War II. Hospitalization of men with gross stress reactions more often resulted in chronic invalidism or disability than in cure. Treating such patients in forward areas with reassurance and supportive treatment that was geared to early return to duty was much more effective.

Grinker used narcosynthesis in the North African theatre. Amobarbital (sodium Amytal) or pentobarbital (Pentothal sodium) was administered continuously until the patient's consciousness and awareness became clouded, but he was still able to maintain contact with the physician. Resistance to recall of the traumatic experience was thus removed, and the patient was permitted and encouraged to express his feelings directly rather than by the indirect neurotic symptoms. Hypnosis was also used in a similar fashion.

For most, the best treatment was prompt treatment administered as close to the individual's unit as possible, avoidance of a hospital atmosphere, and maintenance of an optimistic attitude that the soldier would be able to return to duty in a few days. Creature comforts were attended to as much as possible. Opportunity for bathing—generally a shower—rest with or without sedation, good food, reassurance, and an opportunity to talk about fears, guilts, and experiences were generally sufficient for most men to reintegrate sufficiently to return to duty.

Ordinarily in civilian life individuals are advised by their physicians to avoid those situations that would be likely to precipitate a recurrence of their illnesses. In the service, the role of the physician as a member of the fighting force is to preserve manpower and further the achievement of the group goal rather than the individual's welfare. Consequently, a man who has recovered from a gross stress reaction is returned to the very situation that initially caused his breakdown. This is the equivalent of sending a soldier who has recovered from a wound back to duty where he may not only be wounded again but be killed. This point of view was very difficult to achieve for some physicians who identified with their patients and tried to protect them from further harm.

Prognosis

With prompt treatment in accordance with the principles outlined above, a large majority of patients were returned to duty. Where a somewhat protected

situation was required, some other less stressful assignment was arranged. Those men whose symptoms persisted and were present to a disabling degree were hospitalized for further treatment—milieu therapy, group therapy, individual psychotherapy, subcoma insulin treatment, sedation, and occupational therapy—as indicated. A fraction of this group never recovered sufficiently to be returned to duty and received medical disability discharges. Convalescent hospitals were used extensively toward the end of World War II to assist men further in readjusting prior to being discharged. Dramatic symptomatic improvement was seen in many, but there were many questions about the ultimate prognosis of the approximately 850,000 neuropsychiatric admissions to service hospitals in World War II.

A follow-up study of a random sample of men who had been hospitalized or lost time from duty because of psychoneurotic reactions showed that 90 per cent still had some symptoms 5 or 6 years later. The vast majority, of course, had returned to civilian life and civilian pursuits. Irritability, anxiety, gastrointestinal complaints, restlessness, and headache were the symptoms most commonly reported. For the most part, these symptoms were alleged to have originated in service in association with the breakdown and only to a small degree in the preservice period.

Most men described their health at follow-up as somewhat poorer than at entry into the service but better than at separation; 14 per cent reported that they were unable to work full time because of continued illness, and some impairment of adjustment was present in approximately 50 per cent of the men; about 20 per cent exhibited evidence of moderate disability, and 8 per cent severe disability on examination. The general trend for the entire group was toward improvement, and 61 per cent had either no

illness or at most a mild neurotic disorder. This was in face of the fact that only 36 per cent had sought any treatment for their emotional disorders, and only 15 per cent from psychiatrists.

It is a sobering commentary that there was no evidence that treatment had played an important role in the general improvement that occurred between separation from the service and follow-up. About 40 per cent of the men thought that they still needed treatment, and a similar percentage were drawing Veterans Administration Compensation for partial disability. Compensation seemed to be playing just a little role in the perpetuation of illness, but this may be because the average payment was quite small.

What became clear was that the psychoneurotic disorders that existed before wartime stress or were outgrowths of gross stress reactions were not static. In general, these men tended to improve.

THE PSYCHIATRIC SYNDROMES

Chapter 29

Psychosomatic Medicine. I: Basic Concepts

29.1 HISTORY OF PSYCHOSOMATIC MEDICINE

HAROLD I. KAPLAN, M.D.

The history of psychosomatic medicine cannot be divorced from the history of medicine, for interest in the close interrelationship between mind and body which is the specific concern of psychosomatic medicine is as old as the interest in medicine itself, and advances in this field antedate the era of Hippocrates. Concomitantly, the development of psychosomatic medicine has a crucial relevance for the history of psychiatry. A detailed account of its evolution within this frame of reference is presented elsewhere in this volume. The major historical trends elaborated therein are summarized briefly here.

Paleopathologists have identified skulls of primitive men with trephine holes, which suggests that early attempts were made to treat disease by facilitating the physical departure of evil spirits from the body. Sigerist further reported, in this connection, that in primitive society "there was apparently no division into physical and mental disease." Rather, medicine adopted a holistic approach to disease in man. Moreover, as noted in Table I, this trend continued: the importance of the interrelationship of mind and body was recognized throughout the periods of Babylonian-Assyrian, Greek, and Roman civilizations and during the Dark Ages as well, although the nature of this interrelationship was distorted by cultural variables.

The Renaissance signaled great advances in mathematics, chemistry, and physics, which had important implications for the progress of medicine through their specific application to microscopy, biochemistry, bacteriology, and pathology. At the same time, however, largely as a reaction to the concept which had dominated the Dark Ages of the psyche as a mystical and irrational force, it was no longer considered the proper concern of medicine and was relegated to the province of religion and philosophy instead. In other words, in contrast to the tremendous growth and progress in medicine during this period, interest in psychiatry and

the role of psychic determinism in physical as well as mental disorders diminished.

Only after Freud had made the revolutionary discoveries which led to an increased awareness of the importance of emotions in producing mental and bodily disturbances was this trend reversed. In the past 30 years, Freud's early formulations have undergone considerable modification. Today the concept of psychosomatic medicine has been expanded to refer to the unique interaction of psychological and somatic factors in producing health as well as disease states.

Definition

The term "psychosomatic" was first used by Heinrich in 1818 when he discussed psychosomatic factors in insomnia and then was popularized by the German psychiatrists Jacobi and Nasse. Over the years, the term "psychosomatic" gained considerable popularity and has come to represent a point of view about the importance of psychic factors in medicine and also to encompass a large number and variety of psychogenic medical disorders such as conversion hysteria and diseases with psychophysiological manifestations like peptic ulcer.

In 1952, the American Psychiatric Association in its standard nomenclature recognized the ambiguity in the use of the word "psychosomatic" and coined the designation "psychophysiological autonomic and visceral disorder" to designate specific disorders of various organ systems. In the standard nomenclature these psychophysiological disorders are described as follows:

The symptoms are due to a chronic exaggerated state of the normal physiological expression of emotion. . . . Such long continued visceral states may eventually lead to structural changes.

This group includes the so-called 'organ neuroses.' It also includes some of the cases formerly classified under a wide variety of diagnostic terms such as 'anxiety state,' 'cardiac neurosis,' 'gastric neurosis,' and so forth. . . .

Today in psychosomatic medicine the role of emotional factors in producing or aggravating certain organic visceral diseases, such as peptic ulcer, is generally accepted. However, the exact mechanism of the psychosomatic interaction is a subject of controversy and is discussed elsewhere in this area.

TABLE I
History of Psychosomatic Medicine

Date	Historical Period	Psychosomatic Orientation
10,000 B.C.	Primitive society	Disease is caused by spiritual powers and must be fought by spiritual means: the evil spirit which enters and affects the total being must be liberated, e.g., through exorcism, trephination, etc.
2500–500 B.C.	Babylonian-Assyrian civilization	Medicine is dominated by religion, and suggestion is the major tool of treatment. Sigerist: "Mesopotamian medicine was psychosomatic in all its aspects."
400 B.C.	Greek civilization	Socrates: "As it is not proper to cure the eyes without the head, nor the head without the body, so neither is it proper to cure the body without the soul." Hippocrates: "In order to cure the human body it is necessary to have a knowledge of the whole of things."
100 B.C.–400 A.D.	Late Greek-early Roman civilization	Galen's humoral theory postulates that disease is caused by "disturbances" in the fluids of the body. Medicine adopts a holistic approach to disease.
500–1500 A.D.	Middle Ages (Dark Ages)	Mysticism and religion dominate medicine. "Sinning" is the cause of mental and somatic illness.
1500–1700 A.D.	The Renaissance (16th, 17th, and 18th centuries)	Renewed interest in the natural sciences and their application to medicine: advances in anatomy (Vesalius), autopsy (Morgagni), microscopy (Leeuwenhoek). Psychic influences on soma are rejected as unscientific; the study of the mind is relegated to religion and philosophy.
1800–1900 A.D.	19th century	Modern laboratory-based medicine of Pasteur and Virchow. Virchow: "Disease has its origin in disease of the cell." Psychosomatic approach discarded, since all disease must be associated with structural cell change. The disease is treated, not the patient.
1900–present	20th century	Freud's early psychoanalytic formulations emphasize the role of psychic determinism in somatic conversion reactions ("Dora" case). These early concepts are limited to major hysterical conversions; subsequently, Alexander differentiates conversion reactions from psychosomatic disorders.

omy in Western philosophical thought. The purpose of this section is to elaborate on the philosophical aspects of the mind-body problem.

Interactionism

The major theories bearing on the problem fall into three large groups. First, there are the theories based on the principle of interactionism, which states that the mind influences the body and/or the body influences the mind.

The earliest of such theories were those of Hippocrates, the father of medical psychology, who maintained in his famous doctrine of humors that man's temperament was determined by the relative predominance of four liquids or humors—blood, phlegm, black bile, and yellow bile. He taught that the brain was the most potent organ in the body. Although he derived the psychical from the somatic, he also astutely

29.2 THE MIND-BODY PROBLEM

SIMON H. NAGLER, M.D.

The mind-body relationship is a riddle of ancient lineage indeed. Men pondered its complexities long before René Descartes firmly established this dichot-

recognized that the emotions in turn could have physical effects.

Centuries later Descartes, considered by many to have inaugurated the modern period in psychology, produced a dualistic interactionist theory, which has profoundly influenced modern thinking on the mind-body problem. Descartes found place in his formulations for both the soul and the body. He believed in a free, insubstantial, and unextended soul and a mechanically operated, material, and extended body. He wrote that the soul "is united to all parts of the body conjointly" and that they interact at the pineal gland. The soul perceives and wills; the body is like a machine. His ideas reflected his interest in physics and the new discoveries in physiology, but he was also strongly influenced by his theological allegiances.

Also included in the first group is the doctrine of epiphenomenalism, which contends that the mental processes are but a by-product of somatic activity and are of no causal significance. This attitude, associated with T. H. Huxley among others, became very popular in the second half of the 19th century because of the development of brain physiology. It reached an extreme form in the dictum of the physiologist Moleschott: "*Kein Gedanke ohne Phosphor!*" (No thought without phosphorus).

Idealism, Materialism, and Parallelism

The second cluster of theories includes the chief monistic philosophical views, idealism and materialism, and the dualistic concept of psychophysical parallelism.

The idealists or mentalists, like Berkeley, assumed that there are only mental events in the universe. Bishop Berkeley's subjective idealism held that there is no such thing as substance for qualities to adhere to, and so there are only qualities or ideas, which can only exist for a perceiving mind. Thus, to be is to be perceived. Pushed to its logical conclusions, this theory could only end in solipsism, the conclusion that the self is the only existent thing and all reality is subjective.

On the other hand, the materialists maintained that only matter exists, and, therefore, only the body exists and is real. This philosophical attitude led the 18th century French physician LaMettrie to conclude that thought was the result of the mechanical action of the brain and the rest of the nervous system. Another 18th century French physician, Cabanis, accepted this notion and called the brain the organ of thought, secreting thought as the liver secretes bile.

Stanley Cobb, who has played an important role in the development of psychosomatic medicine in the United States, wrote that "the only philosophically sound point of view for a physician is . . . a belief that mind is a function of the brain in action, as circulation is a function of the heart, or as contraction is a function of the muscle." Cobb, however, denies that this

view is materialism, possibly because of the ethical and political overtones involved.

The great mathematician Leibnitz, starting with a complex theory of monads as the elements of all being, concluded that all monads are synchronized like watches and that the body and the soul merely constitute a special case of the synchronization of monads in general. This notion is the model for theories of psychophysical parallelism, which hold that mental processes and bodily processes run a strictly parallel course without influence on each other.

Double Aspect Theories

Finally, there is the third group of theories, which profess to offer more sophisticated and more subtle types of solutions to the mind-body problem. These theories challenge either the notion of substance or of causality or of both.

For example, there are the double aspect theories associated chiefly with Bertrand Russell and Gilbert Ryle. Russell postulates that neural events are capable of being viewed in different ways. Mind is body seen from one point of view; body is mind seen from another. Physiology sees one aspect, psychology the other. Mental and bodily terms are but two different languages describing the same phenomena. Ryle attempts to distinguish between the something and the way or style in which it exists, an obvious double aspect approach. There is also an organism-response theory, which conceives of mental processes as a distinct kind of response made by an organism interacting with its environment.

Currently Held Theories

What are the main ideas currently held in the Western world? In daily unreflective life, most people are unthinkingly interactionist. Scientists and technicians generally seek to explain human behavior in terms of physical events—neurophysiological, biochemical, etc. Among clinicians, there are those who employ psychological terms like "self," "traits," etc., but who nonetheless cling to the possibility of ultimate explanations to be found elsewhere. In this group, however, there are some who would consider an ultimate explanation in purely physical terms repugnant. Finally, among those interested in scientific method in psychology, some consider the mind-body problem as philosophically senseless and scientifically wasteful of time and effort. Others feel that recent theories, such as those of Russell and Ryle, may be a better approach to psychological theory and practice.

A quotation from a recent text on studies in science can best sum up the prevailing intellectual atmosphere: "Tough-minded scientists tend to relegate the mind-body problem to the limbo of speculative metaphysics. Perhaps after trying a bit, but with questionable success, to square themselves with the puzzle, they usually take one or the other of two attitudes. Either

the puzzle is left to the philosophers to worry about, or else it is bluntly declared a pseudo problem not worth pondering by anybody... it is truly a cluster of intricate puzzles—some scientific, some epistemological, some syntactical, some semantical, and some pragmatic" (Feigl).

29.3 CURRENT CONCEPTS OF PSYCHOSOMATIC MEDICINE

HELEN S. KAPLAN, M.D., Ph.D.

HAROLD I. KAPLAN, M.D.

The importance of a theoretical model extends beyond its academic value, for clinical transactions and research design are influenced thereby. Consequently, it is noteworthy that in the field of psychosomatic medicine, no single theoretical model is considered entirely satisfactory at present. There are basic areas of agreement; at the same time, however, a number of crucial issues are still regarded as highly controversial.

An attempt will be made in this section to review current theoretical models in this field and to summarize some of the concepts upon which modern psychosomatic thought is based.

Basic Concepts

Physiological concomitants of emotion. In 1935, Franz Alexander proposed a theoretical model to explain the mechanism of psychophysiological disorders which underlies much of the current clinical work and research in this area.

Alexander's key contribution to psychosomatic medicine was the concept that psychosomatic symptoms result from the physiological concomitants of psychic

conflict and trauma. This core concept has been elaborated and clarified as follows. Alexander postulated, first, that emotional arousal gives rise to profound physiological reactions, and he conceived of these physiological concomitants of psychological stress as crucial intervening variables in the development of psychosomatic symptoms and disease. More specifically, under ordinary conditions, the somatic concomitants of acute grief, range, or anxiety will not lead to adverse physical consequences in the healthy individual. On the other hand, however, there are certain individuals who are organically vulnerable to the physiological concomitants of affect and may develop psychophysiological disorders as a consequence of emotional arousal. Organic vulnerability is a crucial but variable factor in the genesis of psychosomatic illness. Some patients are highly vulnerable to almost any sort of emotional arousal, while others have a lesser degree of vulnerability and will develop symptoms only when the affective reaction assumes a pathological form and is excessively severe or chronically unrelieved. In general, psychophysiological disorders are most likely to develop when there is a high degree of organic vulnerability together with a substantial emotional disorder.

Differentiation of psychophysiological and neurotic symptoms. In addition, Alexander differentiated between conversion reactions and psychophysiological disorders and thereby ended the confusion which had resulted from the inappropriate application of the same conceptual models to both types of disorders. Previously, both reactions had been thought of as essentially similar neurotic conditions; however, psychophysiological disorders are no longer equated with neurotic symptoms. Admittedly, clinical examination of the psychosomatic patient often reveals that the source of the underlying emotional state can be traced to the patient's neurotic conflicts and pathological object relationships. However, the actual psychosomatic symptom does not have symbolic significance; nor does it serve as a direct defense against anxiety, two qualities which are generally thought to characterize neurotic symptoms. Indeed, it is the *failure* of psychological defense mechanisms to protect the individual against excessive affective arousal that precipitates the onset of the psychosomatic disorder. These considerations are of more than theoretical interest; they have implications for the psychiatric treatment of psychosomatic disorders.

Concept of psychic-somatic unity. Implicit in earlier theoretical models was the belief that psychic and somatic phenomena represent discrete processes. Thus, the somatic concomitants of psychic processes in themselves were often regarded as pathological phenomena. In contrast, according to current opinion, psychic and physiological variables represent different aspects of the unitary phenomenon of affect. Accordingly, physiological responses are seen as intrinsic con-

comitants of emotional arousal. Furthermore, recent evidence suggests that these physiological and psychological variables are constantly engaged in reciprocal interaction. Thus the same psychological situation that evokes an emotional response also evokes a hormonal response as an intrinsic component of the total reaction. The increased hormonal level, through its action on the brain, may then produce modifications in the individual's behavior, which in turn further affects hormone secretion, and so on.

In further support of the hypothesis of psychosomatic unity, recent research findings indicate that the brain structures which control emotions and visceral functions are identical, or closely related. Fear, anger, sexuality, as well as the functioning of viscera and glands, are all regulated by limbic and hypothalamic structures that operate on cortical as well as subcortical levels of neural organization. The precise nature of the interrelationship between physiological and psychological factors in health and disease has not yet been fully clarified. However, the study of the neurophysiological correlates of psychic and somatic functions has become the focus of increasing interest and activity, and it may be speculated that data deriving from this field will ultimately facilitate the understanding, prediction, and control of psychosomatic phenomena.

Concept of multicausality. Implicit in the earlier medical model of disease was the view that ill health was the result of the action of a single pathogenic agent on a host which remained relatively constant. In contrast, the modern model of disease invokes the concept of multicausality. More specifically, medical illness, including psychosomatic illness, is believed to result from the complex interaction of a number of determinants which operate on organic, environmental, and psychological levels. Thus, many individuals who suffer from chronic anxiety will *not* develop psychosomatic disorders, for the physiological concomitants of emotional arousal are necessary (but not sufficient) determinants of psychophysiological disorders. In other words, while psychic factors play a significant role in the etiology of psychosomatic disorders, psychic factors are not the *only* causative determinant. They interact with somatic factors, such as constitution, nutritional status, and organ pathology, to produce the final disease state.

To illustrate, peptic ulcer is believed to result from the erosive effects upon the duodenal mucosa of excessive hydrochloric acid secretion, which is a physiological concomitant of chronic emotional arousal. However, apart from the fact that he is exposed to environmental stress, the ulcer patient, in addition, has a constitutionally vulnerable duodenal mucosa, an excessive parietal cell mass, and, according to some authors, a specifically vulnerable (oral) psychological organization.

Origin of organ susceptibility. As mentioned above, psychosomatic patients are considered to be

organically vulnerable to the physiological concomitants of emotional arousal. However, there is some difference of opinion as to the pathogenesis of this somatic susceptibility. Some authors attribute organ susceptibility to physical trauma; others feel that early adverse psychological life experiences predispose to vulnerability. At present, there is a growing tendency to consider the predisposition to disease in specific organs to be constitutionally determined. The fact that there is a high familial incidence of certain psychophysiological disorders, as well as the findings by several investigators of psychophysiological tendencies very early in life, would seem to support this viewpoint. For example, Mirsky discovered gastric hypersecretion in some neonates and inferred from these data that these infants were genetically susceptible to the development of certain personality traits and to a high risk of peptic ulceration as well.

Theoretical Models

In general, the basic concepts described above are accepted by the great majority of workers in the field. However, the interpretation of these concepts in terms of certain theoretical issues and their implications for clinical practice and research are subject to continuing debate.

One such highly controversial issue in psychosomatic medicine concerns the question of "symptom choice," that is, the reason why one patient develops a peptic ulcer, for example, and another rheumatoid arthritis. In fact, current theories of psychosomatic medicine may be classified according to their position on this issue, as reflected in one of three variations of the basic model illustrated in Figure 1.

(1) According to the "specificity" model, specific psychic events lead to specific affective states and hence to specific psychosomatic symptoms or diseases. (2) The "nonspecific" model encompasses those theories which state that any (i.e., nonspecific) stimulus capable of causing psychic distress may evoke a diffuse affective state (i.e., chronic anxiety), which may then result in a psychosomatic symptom or disease, the nature of which is not predictable from the psychic variable. (3) Finally, the theories subsumed under the third theoretical model of "individual response specificity" postulate that a wide range of stimuli may evoke a pattern of affective arousal which is highly specific for each individual. Concomitantly, the type of psychosomatic symptom the individual develops will depend primarily on his specific response pattern, rather than on the nature of the stimulus. The differences in these three theoretical models are outlined in Figure 1.

A review of the voluminous clinical and experimental data which have been accumulated to support or refute each of these theoretical positions lies beyond the scope of this section. However, the concepts on which each model is based, as well as the assumptions held by the leading proponents of each regarding vari-

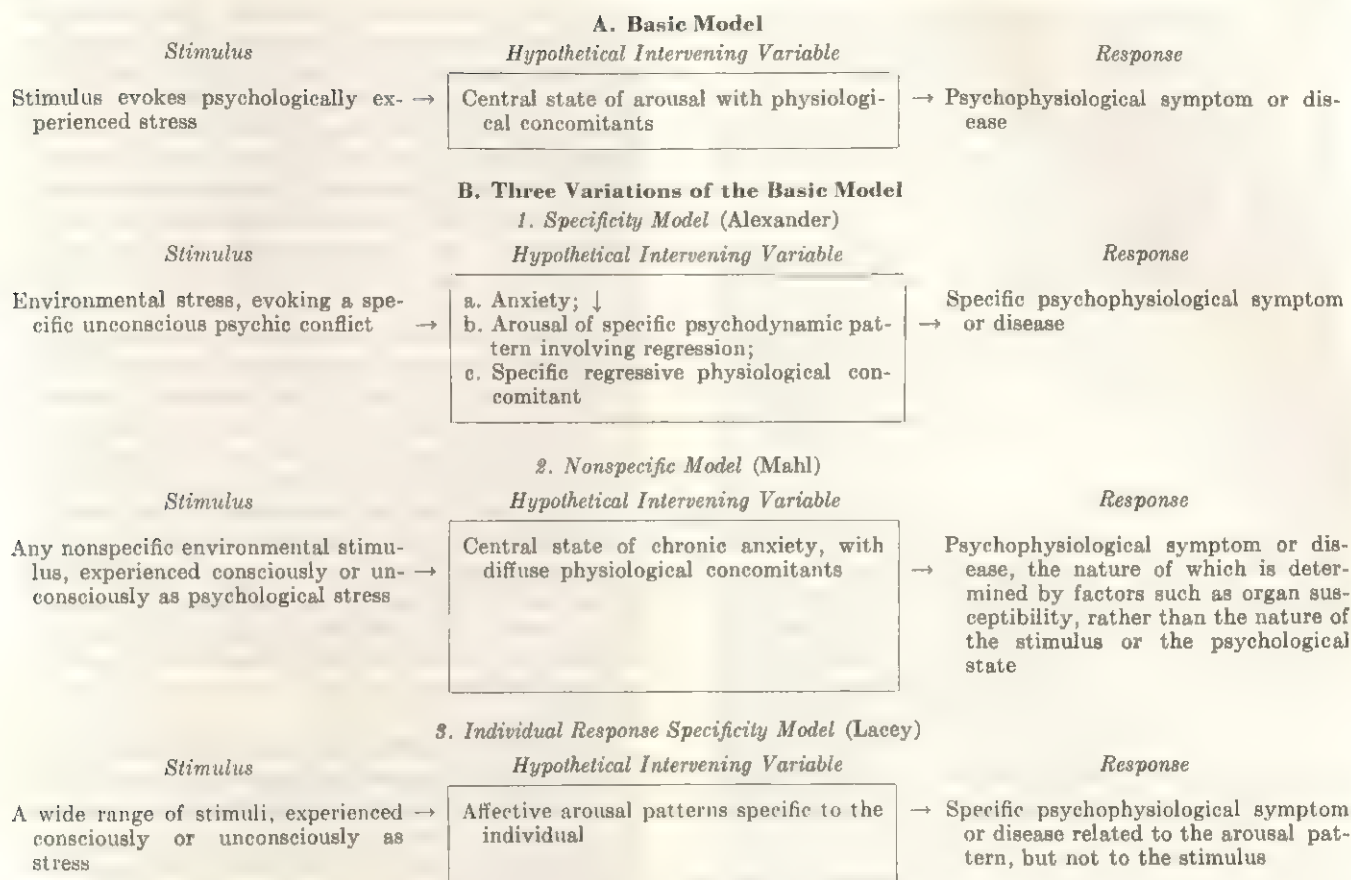

FIGURE 1. Theoretical models of the psychosomatic process.

ous key theoretical issues in psychosomatic medicine, are summarized briefly below.

Specificity model. According to this group of theories, *specific psychopathological events produce specific psychosomatic symptoms*. Leading proponents of the specificity viewpoint include Flanders Dunbar, Stewart Wolf and Harold Wolff, and Franz Alexander.

Flanders Dunbar. Dunbar attempted to correlate specific manifest "personality profiles" with the occurrence of specific psychosomatic disorders. For example, she hypothesized that the "hard, driving, executive type" of personality was particularly vulnerable to coronary artery disease. Subsequent clinical investigations have failed to support this theoretical position.

Stewart Wolf and Harold Wolff. These workers have made a significant methodological contribution to the field of psychosomatic medicine by developing techniques to enable investigation of psychophysiological correlations. By means of these techniques, Wolf and Wolff studied the relationships between various physiological and psychic parameters in healthy subjects as well as in patients suffering from a wide range of psychosomatic disorders. They observed physiological reactions in normal as well as in diseased organs, such as the colon, stomach, and nose, during various emotional states. On the basis of their

findings, they attempted to correlate pathological, physiological, and psychological variables. Wolf and Wolff also evoked a specificity hypothesis to interpret their data. For example, they suggested that specific psychic adaptational patterns of "grimly holding on" or "riddance" might account for the development of psychogenic constipation and diarrhea, respectively. There is no question that this approach has yielded valuable data. However, Wolf and Wolff have been criticized on the grounds that they have overemphasized the manifest content of behavior and neglected important psychodynamic considerations, such as unconscious motivation.

Franz Alexander. Of the group of theoreticians who ascribe to the specificity model, the most influential are those who derive their theoretical frame of reference from Freudian psychoanalysis and utilize such controversial constructs as "regression," "the unconscious," and the "stages" of psychosexual development. The quality of the patient's object relationships is emphasized as a particularly crucial psychological variable in the genesis of psychosomatic disorders.

According to Alexander, the most prominent member of this group, the arousal of specific unconscious psychopathological conflicts results in specific psychosomatic symptoms by virtue of the following

mechanism, described here in simplified form: a traumatic event evokes an unconscious neurotic conflict, which is experienced by the patient as anxiety. According to Freudian theory, anxiety is a danger signal which warns the ego to marshal its defenses against the emergence of dangerous repressed impulses and fantasies. In the psychosomatic patient this psychodynamic process involves "regression" to an earlier stage of psychosexual development and a more primitive mode of relating to objects—to the stage at which the conflict originated, or the stage at which the patient is "fixated." This psychic regression is accompanied, in turn, by specific physiological concomitants, in the form of physiologically immature (and pathogenic) patterns of arousal. Alexander termed the physiological aspects of this process "regressive innervation."

For example, according to this viewpoint, peptic ulcer patients invariably suffer from unresolved unconscious conflicts involving dependency, which have their roots in the oral period. When this neurotic conflict is reactivated by some external frustration, the patient regresses to the oral receptive stage, which is characterized by the unconscious wish to be fed by the mother. The physiological concomitant of this pathological regression takes the form of gastric hyperfunction. If such a psychophysiological constellation is chronically activated in an orally fixated patient with a vulnerable duodenal mucosa, peptic ulcer may result. But, above all, according to Alexander's school of thought, peptic ulceration cannot develop in the absence of this specific conflict; this is essentially what is meant by "specificity."

As mentioned earlier, the regression hypothesis is generally accepted by analytically oriented authors. However, the concept of *partial ego regression* was introduced recently to account for the clinical observations that all psychosomatic patients do not manifest regressive phenomena in terms of aims or objects.

Several authors have contributed experimental and clinical data to support the thesis that specific psychodynamic patterns may have specific physiological concomitants. For example, in his studies of Army personnel, Mirsky found that high rates of gastric secretion were correlated with dependency problems. Similarly, Engel's clinical studies have led him to postulate that during childhood patients who later suffer from diseases of the bowel were exposed to a specific type of pathological mother-child relationship which predisposed them to excessive physical and psychological vulnerability to the effects of object loss in later life.

In contrast, other clinical and experimental findings seem to be incompatible with the specificity position: (1) Patients who demonstrate any one of a variety of psychosomatic disorders typically present a wide range of psychodynamic problems and psychiatric diagnoses which vary from normal to psychotic. (2) Although there is some disagreement in this regard, in general,

a patient's psychological problems cannot be predicted from the nature of his psychosomatic symptom, or vice versa. (3) Furthermore, research studies have shown that certain psychophysiological reactions which are central to the specificity theory, such as gastric hypersecretion, can be predictably evoked in animals exposed to nonspecific stress. Presumably, it would be difficult to account for the occurrence of psychosomatic disorders in animals on the basis of the psychoanalytic specificity theory, which rests on the assumption that complex symbolic processes, such as fantasies and unconscious conflicts, are operative in the genesis of psychophysiological disorders. If it can be further assumed that the psychosomatic process is similar in man and in animals, then the validity of the psychoanalytic specificity hypothesis is clearly open to question. (4) Finally, the specificity theory postulates the same "specific" etiological psychic variables for a wide range of psychosomatic disorders. Thus the same psychological problem, for example, pathological dependence on and loss of a significant love relationship, is considered of crucial etiological significance in such diverse disorders as ulcerative colitis, ileitis, asthma, rheumatoid arthritis, and some of the skin disorders.

Nonspecific model. At the other end of the theoretical scale is the so-called "nonspecific" model. It is the consensus of opinion of workers who subscribe to this theoretical position that sufficient data is not yet available to warrant conclusions regarding organ choice, that is, why one patient will develop peptic ulcers, for example, and another hypertension. This school further contends that at this incomplete stage of our knowledge, hypotheses concerning the genesis of organ choice in psychosomatic disorders have a very low probability of being correct. Consequently, this group of theories deals with psychophysiological relationships in more general terms than do the "specific" concepts.

More precisely, according to the nonspecific model, *psychosomatic symptoms are causally related to psychically experienced stress in general, rather than to specific psychological factors.* Mahl's theory, which is representative of the nonspecific viewpoint, states, first, that any stressful event may evoke a state of chronic anxiety. Second, the physiological concomitants of such anxiety will be identical, whether the anxiety results from a realistic threat intrinsic to the environment, and clearly perceived as such, e.g., bombing in wartime; or an event which is threatening primarily on psychological grounds, e.g., a competitive examination in medical school; or a conflict involving a love object in which event the patient may be only dimly aware of the source of his anxiety which may best be understood in subtle psychodynamic terms.

Chronic anxiety states and psychophysiological disorders have been experimentally evoked in man and animals by a variety of stressful stimuli. Selye and Mahl, among others, have studied the physiological

concomitants of such experimentally evoked chronic anxiety states, as well as the chronic anxiety states which are evoked by traumatic life situations. Some of these investigators regard physiological reactions, such as gastric and cardiovascular hyperfunctioning, and hormonal changes, such as increased adrenal steroid secretion, as universal physiological manifestations of chronic stress; and they consider them to be crucial intervening variables in the development of psychosomatic symptoms and diseases.

As mentioned above, in contrast to the specificity model, the nonspecific theory postulates that the nature of the psychophysiological symptom cannot be predicted on the basis of specific psychological considerations. In general, psychosomatic disorders can be precipitated by any event which evokes excessive emotional reactions. However, in clinical practice the onset of such disorders is often associated with a breakdown of psychological defenses which ordinarily protect the patient from intensive emotional arousal. Such disruptions in psychological defense functioning are likely to stem from the patient's conflicts surrounding his relationships with other people—conflicts which may be “unconscious” or, at any rate, are not perceived clearly. Admittedly, psychodynamic considerations, such as regression, unconscious motivation, disturbances in object relationships, and the breakdown of psychological defenses may be important for the understanding and treatment of the patient's *psychological* problems. However, according to the nonspecific theory, such psychodynamic considerations do not exert a specific influence on the genesis of psychophysiological disorders. Rather, as mentioned above, according to this viewpoint, organ selection may depend on factors which have not yet been determined, such as constitutional organ susceptibility and early experiences which involved the learning of pathological responses.

Mahl's nonspecific concept has been criticized on theoretical grounds as being too general to be useful. However, a virtue of this approach is that it is consistent with the extensive clinical and research data that fail to support the specificity hypothesis. On the other hand, the nonspecific theory has been criticized for suggesting that the physiological concomitants of chronic anxiety are identical in all persons, under all circumstances. This viewpoint fails to account for the marked individual differences in the physical manifestations of affect that have been observed, and that seem to be of some importance in organ selection.

Individual response specificity model. The individual response specificity theory, which was formulated by several workers, including the Lacey and Malmö, differs from the nonspecific model described above in that it does not postulate a generalized affective state, i.e., chronic anxiety, which is similar in all individuals, although it may be evoked by a variety of stimuli. It differs from the specificity position as well, in that it does not assume a correlation between specific

patterns of affective arousal and specific psychodynamic or behavioral factors.

According to the response specificity model, *individuals tend to show highly characteristic and consistent physiological patterns of emotional arousal which may be evoked by a wide range of stimuli and which are associated with the development of specific psychophysiological disorders.* In other words, unless they are extraordinarily intense, affective arousal patterns are not generally diffuse, but select specific foci of activation.

While one individual may react with increased tension of the head and neck musculature to pain induced by electric shock, embarrassing questions, or a frustrating experimental task, another subject will react to the same stimuli with an increase in gastric acid secretions; there are “gastric reactors,” “hypertensive reactors,” “cardiac reactors,” etc. Moreover, some individuals show a typical hierarchy of responses and may react with different patterns in different situations. Thus, for example, a patient may characteristically respond with diarrhea to one kind of stress, such as danger of physical injury, and with a headache to sexual frustration. Malmö has presented evidence which would seem to indicate that these different response patterns are associated with specific psychosomatic symptoms and diseases: “muscle reactors” develop headaches; “cardiovascular reactors” complain of palpitations and chest pain.

Studies of individual specific reaction patterns have a bearing on the regression hypothesis discussed earlier. The emotional reactions of adult psychosomatic patients tend to show specific physiological foci of activation, in marked opposition to the diffuse and immature reactions of infants. Moreover, an individual's characteristic response pattern is established in early childhood and is highly consistent over time. It follows, then, that adult psychosomatic disorders are accompanied by firmly established psychophysiological responses which do *not* represent a return to earlier reactions. The concept of physiological regression as a necessary condition for the development of psychophysiological disorders is not supported by these findings. However, these considerations do not necessarily pertain to *psychological* regression. The return to earlier modes of adaptation in the face of stress, which is frequently encountered in psychiatric as well as psychophysiological disorders, is a separate issue.

As mentioned earlier, patterns of affective activation, and their associated psychophysiological disorders, do *not* seem to be closely related to specific psychic determinants. Consequently, they are not readily predictable on a psychodynamic basis. Moreover, the precise factors in the developmental history of the patient which determine the nature of his specific response pattern and consequent disorder are not yet clear.

The individual response specificity theory is compatible with a wide variety of theoretical orientations,

which range from psychoanalysis to physiology. In addition, although this model, in contrast to the non-specific theory, takes into account the possibility of marked individual differences in the manifestations of emotional arousal, it is consistent with the data which support the concept of nonspecificity. For these reasons the individual response specificity model has been accepted by an increasing number of workers in the field. To date, it has been applied with highly interesting results to the study of cardiovascular disorders and headache.

Current Status of Psychosomatic Theory

Each of the theoretical models described herein has yielded valuable insights and data; yet none can adequately account for all of the available data in the field. In any event, it may be fallacious to assume that any one theoretical model could satisfactorily explain psychosomatic disorders as diverse as peptic ulcer and amenorrhea, for example. Consequently, no one theoretical model has been accepted unanimously by all the investigators and clinicians currently engaged in the field of psychosomatic medicine. This diversity of theoretical predilections is reflected in the following chapter, which deals with specific psychosomatic disorders. Thus, peptic ulcer, psychosomatic skin disorders, rheumatoid arthritis, and psychosomatic gynecological disorders are discussed by Rosenbaum, Engels and Wittkower, Ludwig, and Klein, respectively, all of whom ascribe to the specificity viewpoint. This theoretical commitment is reflected by their emphasis on the role of specific psychic determinants in the etiology of the disorders with which they are concerned. On the other hand, Stunkard's section on obesity, Kapp's on pain, Reiser's on cardiovascular disorders, and Cleghorn and McClure's section on endocrine disturbances are representative of the individual response-specific and nonspecific approaches to psychosomatic problems. Although these authors differ with regard to their basic concepts of psychopathology, they share the opinion that the same psychosomatic disorder may occur in patients with varying psychiatric problems, i.e., that specific psychosomatic disorders are not related to specific psychic variables.

Suggested Cross References

The psychophysiological disorders cited in this section are discussed in detail in Chapter 30. The terms used in this discussion that derive from psychoanalytic theory, such as "ego," "psychological defenses," "regression," and "psychosexual stages of development," are defined in Section 6.1, on classical psychoanalysis. The physiological concomitants of emotional arousal, which are believed to be crucial variables in the development of psychosomatic disorders, are described in detail by Malmo in Section 29.4. Further information regarding the closely related brain mechanisms involved in emotional arousal and visceral functioning

is contained in Sections 2.7, 2.8, and 2.9 on neurophysiology and neuroanatomy in Area B, on the basic behavioral sciences. Finally, the psychophysiological disorders are compared to other psychogenic somatic complaints in Section 23.2 on conversion reactions and also in Section 31.1.

29.4 PHYSIOLOGICAL CONCOMITANTS OF EMOTION

ROBERT B. MALMO, Ph.D.

Acute Emotional Arousal

Careful physiological recordings made with sensitive instruments invariably show measurable changes concomitant not only with reaction to an emotion-producing situation but with reaction to any significant change in the environmental situation. Reaction to strong and repeated painful stimulation is accom-

panied by autonomic nervous system (ANS) changes, generally (but not invariably) in the sympathetic direction, as described in the classic work of Cannon. But very similar shifts in physiological levels may be observed in persons working at a task under high incentive conditions. In fact, the degree of incentive or motivation is generally reflected in the level of physiological activation.

For reasons such as this, Duffy proposed that the distinction between emotion and motivation was dispensable. Although much can be said in favor of this point of view, it lacks general acceptance in its most extreme form. On a strictly operational basis—that is, in terms of the magnitude of the over-all physiological activation—the intensity of two reactions may be judged to be very nearly the same, but the directional aspects of the reactions will be very different, and this difference makes it necessary to retain both terms: emotion and motivation.

Intensity and direction of change. The distinction between intensity and direction in behavior, long stressed by Duffy, is of major importance. In general, the intensity of an emotional reaction may be gauged by recording various physiological measures. A strong emotion, such as that experienced by a patient discussing a sensitive topic during psychiatric interview, is reflected in the physiological recordings. In general, the stronger the emotion, the greater is the over-all physiological activation. Physiological recordings that have been successfully taken from human subjects during psychiatric interview or under similar conditions include the following measures: cardiovascular, respiratory, skin conductance, gastrointestinal, electromyographic (EMG), and electroencephalographic (EEG). ANS reactions such as these are usually in the sympathetic direction. But there are many instances of dissociative reaction. For example, the majority of subjects may show heart rate (HR) rise in a particular situation, but some subjects may actually show HR fall. Such HR fall is dissociative if, as often happens, these same subjects simultaneously show changes in the sympathetic direction in other physiological measures, such as increased respiration rate and pupillary dilation.

In reporting direction of physiological change, considerable caution is required. ANS reactions, especially cardiovascular reactions, are generally polyphasic in character: a change in one direction is followed by a compensatory change in the opposite direction. In some cases the compensatory reaction may predominate over the initial reaction. A striking example of this kind is vasovagal (vasodepressor) fainting, in which the faint itself, characterized by low blood pressure and bradycardia, is the second phase of a diphasic response, the first phase being characterized by rapid or rising HR and by rising blood pressure, especially diastolic. Vasovagal fainting has been observed in persons donating blood, in persons having a simple venipuncture, and in patients undergoing pneumoen-

cephalography. Special attention to the polyphasic character of the physiological change is especially required where the change is a distinct and relatively brief reaction to an abrupt, traumatic, or otherwise forceful stimulus. With less forceful but still effective stimulation the physiological changes are more gradual, there being a relatively slow upward shift to higher levels, as a rule. An example of such a shift in level is that seen in a psychiatric interview when a topic is introduced cautiously and then is slowly developed over a period of some minutes.

Individual differences. Individual differences in physiological reaction are of considerable importance. There is evidence that some individuals tend to show what has been called sympathetic dominance and that others tend to show parasympathetic dominance. This trait of autonomic balance has been quantified by Wenger et al. The distribution appears approximately normal, with the majority of persons showing a fairly equal balance and only a few persons showing extremely high sympathetic and a few showing extremely high parasympathetic dominance.

Still another kind of individual difference is determined by particular physiological measures that show the greatest relative changes under standard conditions of stimulation. The physiological reaction profile has been found to be highly specific to the individual, remaining quite constant for many individuals from situation to situation and from one time to the next. The Lacey's have shown that these specific individual reactions may remain significantly unchanged for 4 years. These findings in aggregate strongly support the principle of physiological response specificity.

Specificity of physiological reaction to stress is observed with remarkable clarity in patients with complaints of bodily discomfort, such as tachycardia, palpitations, precordial pain referred to the cardiovascular system, and tensional discomfort (including muscular pains and tension headache) referred to the skeletal-motor system. EMG recordings from various muscular areas over the body, for example, show highly specific correlations between sites of peak EMG reaction to stress and sites of muscular discomfort. The term "symptom specificity" was introduced by Malmö and Shagass to refer to these correlations.

Because of such individual differences and for other reasons as well, it is unsatisfactory to rely on only one or two physiological recordings in gauging intensity of an emotional reaction. Contrary to certain popular notions, neither the galvanic skin response (GSR) nor palmar conductance (PC) measure is sufficiently reliable to be *the* measure of emotion.

Situational differences. Although perhaps not as clearly supported by reliable and reproducible research findings as the principle of individual physiological specificity, there is evidence to suggest that the mean pattern of physiological reaction from a group of subjects is determined by the particular situation. For example, there is evidence that the physiological pat-

tern of reaction during fear is different from that during anger. It is clear, however, that the degree and consistency of physiological differentiation between two such states as fear and anger are not nearly so clear as the differentiation between the feeling states that are reported by the individuals experiencing these emotions.

On this basis it seems very unlikely that subjective differences between emotions are based mainly on differentiation between autonomic nervous system patterns of reaction. Effects of the total environmental situation on the central nervous system (CNS) are undoubtedly of far greater importance in the mediation of these behavioral and subjective differences. This is not to say, however, that sensory feedback from the ANS does not enter into the picture. Indeed, in the case of some psychiatric patients with somatic symptoms, when even a mild stress evokes a symptom reaction such as tachycardia and palpitations, the sensations associated with this physiological reaction can be frightening, in some cases even terrifying if there is fear of impending death.

Distressing sensations from muscles tensing under stress in patients prone to muscular discomfort in specific muscular groups were previously mentioned in connection with the principle of physiological response specificity. Figure 1 provides a typical illustration of this phenomenon. Data for the graphs were obtained from a 42-year-old female psychiatric patient who complained of muscular discomfort localized in the left thigh. While the patient was engaged in a tracking task, EMGs were recorded from various muscles

over the body; only those from the left and right thighs are shown in the illustration. Figure 1 shows that, when a loud distracting noise was presented during tracking, tension in the left thigh rose to a very much higher level than the level of tension recorded from the right thigh. As a matter of fact, tension in the thigh muscles on the right (nonsymptom) side of the body actually fell slightly under the activating condition. When tracking was performed under distraction-free conditions, no tensional difference between right and left thighs was observed.

Pathological Anxiety

The term "anxiety" is often used colloquially and in laboratory parlance to refer to acute emotional states, such as fear or apprehension. Here the term refers to pathological anxiety—that is, the emotional responses of pathologically increased intensity and duration that may be observed in certain psychoneurotic patients. Pathological anxiety (henceforward referred to simply as anxiety) may be objectively defined as a tensional state of such severity that work efficiency is interfered with and medical advice is sought. It is characterized by one or more of the following complaints: persistent feelings of tension or strain, irritability, unremitting worry, restlessness, inability to concentrate, and feelings of panic in everyday life situations. These complaints are usually found in a setting of dismay and bewilderment, with the patient striving to understand why he feels the way he does. Often there is an intensely strong urge to action in the absence of any consciously perceived goal commensurate with the high level of activation. Finally, on clinical grounds, it has long been known that anxiety patients are physiologically hyperactive; this group of patients constituted a major source of subjects for the experimental work on symptom specificity described earlier in this section.

With regard to the disproportionately high level of physiological activation in everyday life situations, the symptoms of anxiety are possibly unique among the major symptoms of psychiatric disorder. From Freud's treatment of the problem of anxiety to the present, physiological overactivation is cited as an objective accompaniment of anxiety. Although there are undoubtedly particular cues, certain situations that have special meaning or unconscious significance for each individual and so are particularly effective in triggering off the physiological overreaction in each individual case, it is just as true that there are certain relatively nonspecific stimuli that are effective in evoking physiological overreaction in a large number of individuals suffering from anxiety. In other words, the proneness to overreaction appears to involve a physiological alteration rendering the patient overly sensitive to a wide range of stimuli and situations, many of which almost surely have no connection with the etiological conditions responsible for the development of the physiological alteration in the first place.

FIGURE 1. Comparison between tracking trials with and without auditory stimulation. Mean muscle tension from left thigh and right thigh were measured in a patient with complaint of tensional discomfort in the left thigh. Note that, when patient was performing the tracking task under distraction (loud noise), tension rose in the left thigh but not in the right. (From Malmö, R. B. Activation. In *Experimental Foundations of Clinical Psychology*, A. J. Bachrach, editor, p. 416. Basic Books, New York, 1962.)

Because of the current widespread use of tranquilizing drugs in the treatment of anxiety, it is now extremely difficult to obtain valid physiological data from anxiety patients. For this reason, the reliable physiological investigations carried out before the widespread use of these drugs are particularly valuable in providing relatively artifact-free data.

Startle induced by a strong auditory stimulus was found to be one very effective form of stimulation for physiological differentiation of anxiety patients and normal persons. EMG recording under these circumstances revealed no difference between patients and controls in the immediate reflex reaction to the startling sound, the differences in the EMG reactions of patients and controls coming after the primary period of reflex startle (see Figure 2). In view of results from neurophysiological experiments, a likely explanation of the abnormally high after-reaction observed in anxiety patients is that the sustained tension is due to the failure of a homeostatic mechanism located in the reticular systems. Experiments with animals have demonstrated that, by stimulating certain parts of the reticular systems, it is possible to inhibit motor after-discharge.

Examples of other kinds of physiological dysfunction that were observed in anxiety patients (compared with controls under experimental conditions) are the following: irregularities in motor action, such as finger tremor and respiratory irregularity, and autonomic nervous system overreactivity, such as reactions of blood pressure and heart rate. It is sometimes implied that GSR is specifically sensitive to anxiety, but in general this is not supported by experimental findings.

On clinical grounds it is evident that pathological anxiety is a reversible condition, although in some cases it may persist over long periods of time. Careful longitudinal physiological study of anxiety patients, following them through periods of high anxiety and later through recovery, is very much needed.

From combined clinical, psychophysiological, and neurophysiological observations it is reasonable to suggest *tentatively* that the general overreaction in anxiety may be caused, at least in part, by reversible dysfunction of central regulatory mechanisms such as the brain stem reticular system, especially inhibitory parts of this system.

Depression

The anxiety patient group is virtually unique with respect to the clear correlations between subjective pathology and objective physiological changes. These remarkably positive findings contrast sharply with findings from patients in whom depression is the primary symptom (*not* patients with depression that is *secondary* to anxiety; they are placed in the anxiety patient group). Most physiological studies of patient groups with depression as the *primary* symptom have not revealed significant average deviations from normal. One exception is salivary output, which is de-

FIGURE 2. Muscle tension reaction to startling auditory stimulus. Note that the difference between anxious patients and controls occurs in the period *following* the immediate startle reaction. (Malmo, R. B., Shagass, C., and Davis, J. F. A method for the investigation of somatic response mechanisms in psychoneurosis. *Science*, 112: 327, 1950.)

creased in psychotic depression and in schizoaffective disturbances. Although further positive results may yet be obtained with different tests and measures, present evidence strongly suggests that, from the physiological point of view, primary anxiety and primary depression involve quite different mechanisms. Certainly the evidence is opposed to thinking that they are on the same continuum.

It seems likely that objective study of depression would profit greatly from further cinematographic analysis of postures and bodily movements in depressed patients. On clinical grounds it appears that objective deviations specifically characteristic of depressives may be found in careful analyses of the way in which the patient walks, turns his head and body, and so on, rather than in measurements of ANS changes. Along these same lines, further objective analyses of agitation in depression should be most useful, especially if the observations of bodily movements are combined with physiological recordings. Again, on the basis of clinical observations it would appear that agitation is a symptom that physiologically is significantly different from the condition of general physiological overactivation found in anxiety. But this still remains a question for investigation.

Suggested Cross References

Further comments on physiological concomitants of affective states such as anger, fear, and depression may be found in Cleghorn and McClure's discussion of psychophysiological endocrine functions (Section

30.9). Fundamental concepts regarding the physiology and chemistry of the central nervous system processes involved in emotional arousal are discussed by Doty in his section on the limbic system (Section 2.8) in Area B, on the basic behavioral sciences. The concept of individual response specificity mentioned in this section is discussed further in Section 29.3 on current concepts of psychosomatic medicine.

Chapter 30

Psychosomatic Medicine. II: Psychophysiological Disorders

30.1 PEPTIC ULCER

MILTON ROSENBAUM, M.D.

Definition

In current medical practice, the term "peptic ulcer" encompasses both gastric ulcer and duodenal ulcer. It is true that these syndromes have much in common; however, it is also quite probable that their differences extend beyond anatomical location of the lesion.

For one, duodenal ulcer is more prevalent in men, and in the younger age group; in contrast, gastric ulcer occurs with equal frequency in both sexes. Second, and of marked importance is the high incidence (10 to 20 per cent) of gastric carcinoma which is associated with or occurs subsequent to gastric ulcer, so that, unlike duodenal ulcer, in cases of gastric ulcer the possibility of gastric carcinoma must always be considered. Third, gastric ulcer is associated with normal or subnormal gastric secretion; in duodenal ulcer, gastric secretion (HCl and pepsin) is markedly increased. Finally, clinical evidence indicates that important differences exist in the psychological and emotional correlates of these syndromes, which further justifies their delineation as separate and unique disorders. Specifically, emotional factors are believed to play a more significant role in duodenal ulcer than in gastric ulcer, and this hypothesis is supported by Dragstedt's observations that the division of the vagus nerve abolishes fasting gastric hypersecretion in duodenal ulcer but not in gastric ulcer, and that vagotomy is ineffective in gastric ulcer. Accordingly, with relatively few exceptions, the studies described herein involved patients with duodenal, rather than gastric ulcer.

Epidemiology

Peptic ulcer is considered to be a disease of civilization; it is rarely seen among the natives of such areas as northern India or Java-Sumatra, or in the South African Bantus. Concomitantly, it is more pre-

valent in urban as compared to rural areas, among men in administrative and professional fields, and among high income groups in general, although it is by no means infrequent in lower socioeconomic groups. As mentioned earlier, duodenal ulcer occurs more frequently in men than in women, the current ratio being approximately 4 to 1, with a continuing increase of incidence in men. This difference in incidence on the basis of sex can be attributed primarily to psychological factors and is discussed in detail below in this context.

Clinical Features

The outstanding symptom of peptic ulcer is epigastric pain, which usually occurs between 1 and 4 hours after a meal, lasts for 30 to 60 minutes, and is relieved by food intake or alkalies. The pain is sharply localized in the epigastrium, and in the traditional clinical examination the patient points to the site of the pain with his finger. The pain is most intense in the afternoon and at night, usually during the hours between midnight and 2:00 A.M. The syndrome is further characterized by periodicity and chronicity, with remissions and exacerbations which may extend over a period of time ranging from 10 to 25 years. Diagnosis is made from the patient's history and roentgenological studies.

Some medical authorities also maintain that the tendency for pain to disappear "spontaneously" after 6 months to a year for a temporary period is a classic feature of the syndrome. In fact, however, when adequate attention is directed toward the psychological and social determinants of ulcer, it becomes apparent that, in most instances, "spontaneous" remission (as well as exacerbation) can be related to meaningful emotional events. Neither the disappearance of pain nor its recurrence can, therefore, be considered to represent a "spontaneous" event.

Psychological Determinants

"Specificity" hypothesis. Clinicians have long noted that their patients with peptic ulcer frequently manifest certain typical emotional states and per-

sonality characteristics. Earlier psychological studies were concerned with the description of these personality and character traits and their correlation with the ulcer syndrome. Attempts were also made to correlate acute emotional states, either experimentally induced or occurring in the natural course of the patient's psychological life, with changes in gastric functions. Alexander and his colleagues, using psychoanalytic techniques, investigated the role of unconscious conflicts in ulcer patients, and they were the first to postulate a specific type of emotional conflict in this patient population, namely, a dependent-independent one which stemmed from the persistence of intense unconscious oral receptive tendencies, on the one hand, and their repudiation by the adult ego (shame, pride) or by external circumstances, on the other.

Personality patterns. This author and his associates tested this hypothesis in a clinical study of male ulcer patients seen in a large city hospital. In general, all of the patients in the group studied demonstrated intense parasitic dependent desires, and in each case ulcer symptoms developed when these infantile cravings were denied. Apart from these universal characteristics, the patients studied were divided into three groups on the basis of their manifest personality structures. The first group of "pseudo-independent" patients reacted to deep unconscious dependent cravings by becoming ambitious and successful; that is, they characteristically utilized the mechanism of overcompensation in their actual life relationships. The second group of "passive dependent" patients expressed their dependent desires to a limited degree. And, in general, these patients appeared passive and shy, with marked trends toward feminine identification. Finally, the majority of the patients studied were assigned to the third "acting out" group. The patients in this group expressed their strong oral cravings and demands by their pathophysiological symptoms, as well as by acting out. Characteristically, they overindulged in drinking and gambling, committed acts of delinquency, and were unable to earn a living. Essentially, in terms of personality structure, these patients exemplified the unweaned suckling whose oral needs appear to be insatiable.

Thus, all of the patients studied demonstrated the same unconscious conflict (i.e., dependence versus independence). However, their overt personality patterns ranged from defensive facades of independence to attitudes of parasitic dependence.

The concept initially advanced by Alexander and his associates that ulcer patients demonstrated a specific type of emotional conflict has been supported by many other clinical studies as well. On the other hand, however, the data accumulated to date which fail to support the specificity hypothesis are equally impressive. In brief, the question of the role of specific emotional reactions in patients with ulcer and other psychosomatic diseases is far from settled.

Diagnostic validity. A research project was initiated at the Chicago Institute for Psychoanalysis in 1950 (and is still in progress) to test the validity of the specificity hypothesis based on the "blind" diagnosis of seven "psychosomatic" diseases.

The over-all results to date indicate that in 51 per cent of the cases investigated, the analysts in the research group were correct in their diagnosis of the patient's illness on the basis of psychodynamic formulations. (This finding is in marked contrast to the expected chance results of 14 per cent, or one out of every seven cases investigated.) Of the seven diseases studied, patients in the ulcer group were diagnosed correctly least often—32 per cent as compared to arthritis, which was 51 per cent. Moreover, there was a striking difference in diagnostic accuracy for male and female ulcer patients. Thus, 49 per cent of the group of male ulcer patients were diagnosed correctly, but only 16 per cent of the females. Indeed, it is interesting to note that the poorest performance of the research group involved the diagnosis of female ulcer patients. It should be noted in this connection that Alexander's psychodynamic formulations were, in fact, based on the analysis of male ulcer patients. Clearly, the applicability of the concepts derived therefrom to female patients is open to serious question.

Psychophysiological Correlations

Historical basis. Over 100 years ago, Beaumont recognized that changes in gastric functions were associated with emotional reactions, but he was concerned primarily with observations on the gastric juices, rather than the personality of his subject. However, Cannon's more recent observation that gastric disturbances typically occurred during periods of emotional crisis added great impetus to the study of the relationship between psychological variables and physiological factors. Subsequently, Wolf and Wolff demonstrated the relationship between human gastric functions and various emotional states in their now classical subject, Tom, the man with the gastric fistula. However, of particular importance in this connection was the observation by these workers that situational stresses which were correlated with disturbance in gastric function were not artificially produced but occurred in the natural life setting of their experimental subject.

Current formulations. Mirsky's studies of the etiology of duodenal ulcer, in which he attempted to correlate psychodynamic factors with the function of the peptic cells of the gastric mucosa by measuring the excretion of pepsinogen, represent the most outstanding studies in this field to date. First, patients with duodenal ulcer were shown to have a higher rate of pepsinogen excretion in the urine, and a higher concentration of pepsinogen in the blood, than do subjects who are free of gastrointestinal disturbance. Mirsky's studies of the concentration of pepsinogen in

the umbilical cord blood of neonates further revealed that the pepsinogen concentrations of approximately 12 per cent of the neonates were in the range of those found among adult patients with duodenal ulcer. And studies of identical twins support the possibility that the concentration of pepsinogen in the serum is genetically determined, at least in part.

However, the fact that an increase in gastric secretion is associated with the presence of a duodenal ulcer does not in itself mean that the former is responsible for the latter, or vice versa. A variety of studies suggest that, while gastric hypersecretion is an essential determinant in the etiology of duodenal ulcer, it is not the sole determinant. Rather, gastric hypersecretion is one of several predisposing factors. Thus, it has been postulated that high pepsinogen secretors represent that segment of the population most likely to develop duodenal ulcer if they are exposed to those circumstances which, in turn, give rise to the sequence of physiological events which result in the lesion. On the basis of this formulation, Mirsky concluded that precipitation to duodenal ulcer must be considered in terms of three parameters. The physiological parameter refers to the individual's susceptibility to the duodenal ulceration. The psychological parameter refers to the presence of a relatively specific psychic conflict which induces psychic tension. And, third, the social parameter refers to an environmental event which will prove noxious to the individual. In other words, the individual with a sustained rate of gastric hypersecretion who is exposed to an environmental situation which mobilizes psychic conflict and induces psychic tension is likely to develop a duodenal ulcer.

Experimental validation. Two sets of studies were designed to assess the interaction of the parameters described above in the precipitation of duodenal ulcer. In both studies, the degree of gastric secretion, as gauged by the concentration of pepsinogen in the serum, comprised the physiological parameter. Thus, subjects with serum pepsinogen concentrations 1 standard deviation above the mean value of the adult healthy population were regarded as hypersecretors, while subjects with pepsinogen values 1 standard deviation below the mean were regarded as hyposecretors. Subjects representative of those with the lowest as well as the highest concentration of pepsinogen in the blood were selected, to permit one group to serve as controls for the other. The style of interpersonal interactions, as inferred from psychoanalytic and psychoanalytically oriented anamnestic interviews and from projective tests and other psychological techniques, comprised the psychological parameter. In the first study by Weiner et al., exposure to 16 weeks of basic training at an army camp was the environmental situation which might prove noxious to some subjects, but not to others, and, as such, comprised the social parameter.

The hypersecretor group included a total of 300

subjects. Of these, the 63 draftees with the upper 15 per cent of the serum pepsinogen values were selected for special study. The subjects studied in the hyposecretor group consisted of the 57 men (of a total of 179) with the lowest 9 per cent of the serum pepsinogen distribution.

The first roentgenological examination of the 63 subjects with gastric hypersecretion revealed evidence of a healed duodenal ulcer in 3 cases, and an active ulcer in 1. Of these 4 men who presented evidence of duodenal lesions at the outset, 1 became a disciplinary problem and was confined to the stockade; 1 went AWOL; and 1 completed his basic training without incident; the fourth man, who had the active duodenal lesion, was discharged from the service.

At the second roentgenological examination, which was scheduled from the 8th to the 16th week of basic training, there was evidence of active duodenal ulcer in an additional 5 men who had not manifested any signs of gastrointestinal disorder at the outset of the study. All the subjects who had presented or subsequently developed evidence of a duodenal ulcer belonged to the group of 63 men with high serum pepsinogen values, and within this group 15 per cent of the men in the top 5 per cent of the distribution developed a duodenal ulcer during a relatively brief interval.

In the second long term study by Mirsky, which has been in progress since 1946, the environmental event occurred spontaneously. More specifically, a population of 1,600 children, ranging in age from a few months to 16 years, and 4,460 men and women from various socioeconomic strata were screened, and, as a rule, the 2 per cent of the population with the highest concentrations of pepsinogen in the serum were selected to comprise the hypersecretor group for special study. Similarly, the 2 per cent with the lowest values were selected to comprise the hyposecretor control group. It was assumed that all of the subjects studied would be exposed, to varying degrees, to "normal" and inevitable environmental stress. Although this study is still in progress, a fairly large number of the initially healthy hypersecretors who have been followed for several years have developed the typical signs and symptoms of a duodenal ulcer which have been subsequently confirmed roentgenologically. In contrast, none of the subjects in the hyposecretor group have developed the ulcer syndrome.

Etiological Propositions

In the studies described above the subjects who comprised the apparently healthy hypersecretor group exhibited essentially the same personality structure and the same psychodynamic patterns which had previously been described as characteristic of patients with duodenal ulcer. That is, the group of subjects with high concentrations of pepsinogen in the serum showed intense needs which were principally

oral and dependent in nature. However, the individuals in the hypersecretor group differed from each other in the manner in which they handled these persistent infantile wishes. Such differences are determined by those factors in each person's total life experiences which play a crucial role in personality development. In other words, the ego defense structure unique to each individual will determine his reaction to stressful environmental events.

The precise social event which precipitates duodenal ulcer in the susceptible individual will, of course, vary from person to person. However, these events share one feature in common; namely, they involve the activation of oral and dependency needs and the concomitant frustration of these needs. Thus, in the short term study of draftees, it was correctly assumed that separation from home and the restrictions associated with the basic training period would prove noxious to those individuals who did not possess sufficient ego strength to cope with these frustrations. Similarly, in Mirsky's long term study all the apparent precipitating events were related to the obvious mobilization of fears of loss of love and security, intensification of persistent infantile passive, oral-dependent wishes; the frustration of such wishes, and the activation of what Weisman has referred to as the passivity-activity nuclear conflict.

Role of early oral trauma. The formulation of the dependent-independent conflict in ulcer patients was based on the psychoanalytic concept of trauma during the oral phase of development. Psychoanalytic reconstruction of historical data elicited from patients with duodenal ulcer suggests that these strong dependent wishes have their origin in either parental rejection or overpermissive attitudes in early childhood. Initially, it was thought that these persistent infantile oral-dependent wishes might have a physiological concomitant. That is, they might act as a consistent stimulant to the stomach, leading to gastric hypersecretion. But Mirsky's findings suggest that gastric hypersecretion is genetically determined. This raises the possibility that oral conflicts do not arise only when the infant's oral needs are unsatisfied because of maternal deprivation. Such conflicts may also exist in cases where the mother-infant relationship was a relatively good one, and where the infant's oral drives remained ungratified because they were physiologically insatiable. More specifically, one might speculate that a mother whose ability to gratify the oral needs of her infant would be considered quite satisfactory under normal circumstances may be only partially successful in providing physiological satiation for an infant who is a hypersecretor, with the unfortunate result that such a mother is perceived psychologically as rejecting. Furthermore, the inability of this "good" mother to satisfy or to gratify her infant may induce feelings of frustration which, in turn, will give rise to hostile and rejecting attitudes. It seems likely, therefore, that the degree to which infantile

dependent wishes persist in such cases will depend upon the quantitative aspects of the mother's integrative capacity, as well as on the infant's rate of gastric secretion.

Etiology of peptic ulcer in women. It is well established that in the past 50 years there has been a remarkable shift in the sex incidence of peptic ulcer in Western civilization. Studies conducted prior to 1900 demonstrated, without exception, that peptic ulcer occurred more frequently in women. About 1910 the sex incidence became equal and since 1910 there has been a progressive rise in the incidence of peptic ulcer among men and a decrease in its incidence among women, despite the fact that the over-all incidence of peptic ulcer has remained approximately the same during this period.

Consideration of the factors responsible for this changing sex incidence has important etiological implications. Some authors have attributed this phenomenon to sociological and cultural factors. For example, in the 19th century men were better able, because of their life situation, to express both their aggressive and their dependent impulses: it was relatively easy for them to be active at work and simultaneously to be mothered and cared for by their wives at home. In contrast, while women could satisfy their dependency needs in the home, during this period they were blocked socially from expressing their aggressive or independent impulses. After the turn of the century, however, men were subject to increased social and economic pressures. Economic factors, in particular, contributed to the frustration of their aggressive drives and the mobilization of their dependent wishes. On the other hand, in this new social climate, women could express many competitive independent impulses which had been considered taboo formerly. Modern woman is better able than man to express antagonistic drives such as dependency and independence. She can be openly dependent without undue shame or guilt, or lead an active independent life, or express both drives concurrently, without the need for repression or reaction formation which is so characteristic of men.

As mentioned earlier, Mirsky's findings suggest that the concentration of pepsinogen in the serum may be genetically determined. With specific reference to the changing sex incidence, however, his observation that approximately three men for each woman in the healthy population have a concentration of pepsinogen in the serum which exceeds the mean of the population with duodenal ulcer lends emphasis to the importance of social and cultural factors. Clearly, it is highly unlikely that there has been a sudden shift in the genetic aspect of ulcer which might account for the change in sex incidence. Rather, it must be explained on the basis of psychological and sociological variables.

Several investigators have attempted to describe the psychological characteristics of the female ulcer patient and to identify the etiological factors opera-

tive in the genesis of the disease. This author and his associates studied a group of women with peptic ulcer and found that, in contrast to a group of male ulcer patients, all the female subjects studied exhibited rather severe overt personality disorders. Study findings also revealed that the majority of these female patients had been rejected by their mothers and had turned to their fathers for support. Ulcer symptoms were precipitated when the supportive figure failed them. In another study, 200 women with proven ulcer were divided into three groups: the women in the first group were described as masculine-aggressive; the second group comprised subjects who were considered immature and inadequate; and, finally, the subjects assigned to the third group appeared to accept their feminine role. It was further noted that, prior to the onset of the disease, 69 per cent of the total subject population had undergone a surgical (gynecological) procedure or event (menopause) which interfered with their sexuality, either in fantasy or reality. In the group of masculine-aggressive women who rejected their feminine role, the gynecological trauma was not a significant factor in precipitating the ulcer. In the inadequate immature women, the ulcer had developed after the death or loss of a supportive figure. In the third—and largest—group, the women had accepted their feminine role until the occurrence of the sexually threatening event. Therefore, this was considered to constitute a precipitating factor in the onset of the ulcer. In addition, the onset of the ulcer in this group was closely related to events which mobilized pregnancy fantasies and wishes (e.g., the birth of grandchildren, or pregnancy in siblings).

Treatment

The treatment of patients with peptic ulcer is the domain of the general practitioner, and the primary therapeutic concern is the medical management of the patient. Consequently, from the practical point of view, the psychiatrist's role may be a limited one. In general, he may function as a consultant in selected cases, and, occasionally, he may function as a therapist; for the most part, however, his role is that of clinical investigator.

Medical management. If it is to be effective, the physician-patient relationship must reflect the physician's understanding of the psychodynamics of this illness. Specifically, the physician must be aware of the patient's current crucial areas of conflict, so that he will be in a position to meet the emotional needs of the patient, especially during periods of stress or anticipated stress. The physician should also be aware of the fact that the repressed dependency needs of many patients can be gratified, either directly or indirectly, without necessarily inducing shame, guilt, or resistance in the patient. This can be done by environmental manipulation, such as prescribing a vacation, or enlisting the support of key figures in the

patient's environment. Above all, the physician-patient relationship should evoke a sense of security in the patient. To this end, the physician can manipulate the transference by increasing the frequency of office visits or extending the interview period, for example, and by prescribing medication, and hospitalizing the patient during periods of emotional crisis with the hope of preventing complications. If such procedures, combined with intensive medical treatment, prove inadequate, the patient should be referred to a psychiatrist for more intensive psychotherapy.

Surgical intervention. The possibility of surgical intervention must be considered for patients with intractable symptoms. As a general rule, when a great deal of the patient's psychic energy is bound by his symptoms and by the therapy (diet, etc.), the possibility that surgical intervention will produce favorable results becomes more remote. On the other hand, the less psychic energy bound in this manner, that is, when the patient derives little instinctual gratification from being ill and little secondary gain, the prognosis improves. It has been postulated that surgical intervention for the removal of intractable peptic ulcer symptoms may result in the development of new symptoms. This hypothesis was tested by Browning and Houseworth in a study of two groups of ulcer patients with intractable symptoms. One group of 30 patients was treated by gastrectomy; a control group was treated medically. After gastrectomy, only 43 per cent of the patients in the surgically treated group still had ulcer symptoms. But whereas only 13 per cent of this group had other psychosomatic symptoms as well prior to surgery, 37 per cent manifested such symptoms following surgery. In addition, the incidence of neurotic symptoms increased from 50 per cent to 100 per cent. In contrast, in the medically treated group, the ulcer symptoms remained unchanged, but there were no new symptoms. The authors concluded, on the basis of these findings, that surgical removal of ulcer symptoms appears to result in their replacement by new symptoms in a significant number of cases. In another study, patients with duodenal ulcer who required surgery for intractable symptoms were compared to patients requiring surgery for perforation, hemorrhage, and obstruction. It was found that 90 per cent of the patients in the latter group obtained good results, while only 60 per cent of the intractable ulcer symptoms were relieved. In this study, the most important prognostic factor in the intractable group was the degree to which the patient had been able to satisfy his basic social needs prior to surgery.

Suggested Cross References

In this section the psychosomatic aspects of peptic ulcer are discussed in a "specificity" frame of reference, according to which specific psychological factors are associated with peptic ulcer. For a discussion of alternate conceptual models of psychophysiological

processes, see Section 29.3, on current concepts of psychosomatic medicine. A more detailed discussion of the psychoanalytic concept of orality may be found in Section 6.1, in Area C, on current concepts of personality and psychopathology.

latter, called somatopsychic-psychosomatic because of the role of organic factors in the primary predisposition and of psychological factors in the course, include ulcerative colitis and enteritis, regional enteritis, granulomatous colitis, celiac disease, and irritable bowel syndrome (mucous colitis and spastic colon).

Psychophysiological and Psychogenic Disorders

The eliminative function of the bowel determines its involvement in psychophysiological patterns of riddance and retention, and the conflict between physiological function and the social and interpersonal demands for bowel control and cleanliness determines its role in the psychogenic disorders.

Physiological concomitants of affects. Evacuation of the bowel during fear by man as well as by lower animals was known to the ancients and presumably represents a very primitive reaction to acute stress. During acute anxiety there may be periodic peristaltic rushes, sometimes with cramps and diarrhea. Such diarrhea, which occurs concurrently with the other manifestations of anxiety, typically begins with the rapid evacuation of the formed contents of the lower bowel, which is followed by the more liquid feces of the proximal colon. Three to six watery bowel movements, decreasing in volume over 1 to 3 days, are the characteristic feature, even when anxiety persists longer. This is much less commonly a simple affect concomitant, occasionally accompanying acute feelings of sadness, discouragement, and depression.

Diarrhea that is more than transient or in which the stools show appreciable mucus or any quantity of pus or blood or are greasy and malodorous generally indicates the presence of some other disorder, perhaps unmasked or exacerbated by the physiological effects of the affect. Constipation that begins with or soon after the experience of a depressive affect and becomes chronic may also signify the development of an organic bowel disorder, notably cancer.

Conversion reactions and anal drive. The rich symbolism associated with feces and defecation and the erotogenicity of the anus, plus the fact that its function is learned and partially under voluntary control, predispose the rectum and anus to conversion and anal drive patterns. These include constipation, frequent bowel movements (not usually true diarrhea), rectal spasm, sphincter spasm, rectal sensations, and pruritus ani. The repressed fantasies and the corresponding conversion manifestations include ideas of rectal pregnancy (severe constipation, abdominal distension, followed by a huge evacuation); anal intercourse and homosexual wishes (sphincter spasm, rectal spasm, pruritus ani, constipation, rectal sensations); aggression expressed in soiling terms (constipation, frequent evacuations, pain in the rectum).

Patients manifesting such conversion symptoms are likely to have a predisposition to conversion, and many have the personality features of hysteria. A few,

30.2 INTESTINAL DISORDERS

GEORGE L. ENGEL, M.D.

Patients seen by psychiatrists may exhibit a variety of expressions of disordered bowel function, including cramps, diarrhea, constipation, bleeding, incontinence, pruritus ani, bizarre rectal sensations, and flatus. Some of these are purely psychogenic in origin, some are psychophysiological phenomena, and some are symptoms of organic bowel disorders. The

especially men with such rectal symptoms, may be latently paranoid. Identification with other persons with bowel symptoms may also play a role in symptom choice. The reader is cautioned against making a diagnosis purely on the basis of plausible symbolism without reasonable corroborative data.

In those instances where control of bowel function has played an inordinately important role in infancy and childhood, bowel symptoms, notably constipation and diarrhea, are commonly expressive of psychological trends (drives) deeply embedded in the matrix of the personality. Among these persons, such personality trends as control and lack of control, generosity and miserliness, stubbornness and flexibility, order and disorder, cleanliness and sloppiness may be equated with the corresponding bowel behavior and be so expressed. Such a person may become constipated or have diarrhea when he is called on to give or perform more than he feels capable of, when he is in a messy place, when he should feel angry at someone, or when he feels deprived. These trends are such intimate parts of the total personality structure that they remain largely unconscious and are unlikely to be uncovered except by depth analysis, though they may be clearly revealed in dreams. In classical psychoanalytic terminology, such persons are typically anal characters.

Disorders of elimination secondary to psychopathological states. Certain patients exhibit inappropriate or bizarre patterns of elimination that are secondary to psychopathological states. These differ from conversion reactions in that they represent complex disturbances in the behavior associated with elimination rather than representing the use of a body part or function in a symbolic and defensive manner. Such disturbances may range from inadequate or undifferentiated elimination behavior to behavior that is determined by bizarre, usually psychotic, ideation.

Addiction to laxatives, enemas, high colonic irrigation. Excessive use of laxatives or enemas may be presented by the patient as a thoroughly rationalized behavior or in relationship to some gastrointestinal complaint that is usually explained in terms of the patient's idiosyncratic concepts. Some patients offer such traditional complaints as lack of appetite, nausea, vomiting, eructation, bloating, abdominal rumbling, indigestion, excessive gas, diarrhea, or constipation; others offer bizarre health theories as justification for the urge to purge. But further psychological inquiry often demonstrates that at the basis of the behavior are morbid psychological concepts of something "bad" or destructive within the body, actually displacements of "bad" or disturbing thoughts or fantasies. Accordingly, the patient sees the contents of the bowel as positively bad or dangerous. He may espouse pseudoscientific theories as to the deleterious action of retained feces and utilize extreme measures to clean out the bad intestinal contents. Sec-

ondary nutritional deficiencies and electrolyte imbalances may result. Further inquiry usually establishes that these strange notions are not restricted to the functions of the gastrointestinal system but extend to many other spheres as well. Many of these people also exhibit other eccentricities in dress, manner, behavior, and belief systems and often belong to crank or fringe groups. Some are obviously schizophrenic, and most reveal at least an inclination toward the persecutory delusional attitude of the paranoid.

Encopresis and psychogenic megacolon. Encopresis or fecal soiling—like its urinary counterpart, enuresis, with which it is occasionally associated—represents a complex psychologically determined failure or lapse in toileting. It consists of the passage of stools of normal or near normal consistency into clothes, bed linen, or any receptacle not intended for such purposes. It typically begins in childhood either as a failure to achieve proper toileting or as a loss of previously achieved bowel control and only infrequently extends into adulthood. It takes the form either of the promiscuous and casual expulsion of feces whenever the impulse so moves or of prolonged retention of stool with leakage of feces or periodic huge movements. The latter may be associated with enormous distention of the colon, sometimes designated as psychogenic megacolon.

Anthony identified three prototypes of the encopretic child. The "continuous child" is a dirty child coming from a dirty family, where symptom tolerance is high and where the mother is peculiarly unaware of the child's defecation cues. Continence is simply not achieved. The "discontinuous child" is the compulsive child of a compulsive family, overcontrolled, scrupulous with regard to his habits, secretive and ashamed about his toilet leakage. Usually, the mother is meticulously clean and unwittingly encourages the child to soil so as to provide a scapegoat for her unconscious sadomasochistic impulses. The "retentive child" is one who has undergone severe toilet training to which he responds with a stubborn constipation, which later gives way to encopresis. In the constipation phase, the intense struggle between mother and child may be marked by her insistent use of enemas, suppositories, and cathartics.

Bowel manifestations with psychosis. Extreme constipation may develop during psychotic depression, and incontinence may develop during acute and chronic brain syndromes and schizophrenia. Persistent and bizarre anal and rectal sensations, sometimes frankly delusional or persecutory in character, are occasionally the presenting complaint of a paranoid patient who presents himself to a rectal specialist for treatment.

Somatopsychic-Psychosomatic Disorders

Traditionally called psychosomatic and, according to the American Psychiatric Association nomenclature,

psychophysiological and visceral disorders, these are basically organic disorders in that they involve primary somatic predisposing factors and ultimately distinctive morbid anatomical changes in the involved organs. At the same time these somatic processes seem to contribute directly or indirectly to the development of specific psychological characteristics, which in turn define in a more or less specific way the circumstances that prove psychologically stressful for the individual and hence the psychodynamic conditions under which the organic process may become activated. To fulfill these requirements, the somatic factor must be present and exerting an influence from very early in life, placing it in the category of a genetic, congenital, or early acquired defect. It is in these regards that these disorders differ from those designated more simply as psychogenic and psychophysiological.

Characteristically, such disorders tend to be familial, may appear at any age from infancy to senescence, and, once initiated, run a chronic or remitting course with exacerbations or relapses that may culminate in irreversible structural changes. Psychological factors play a preeminent role in onset, remissions, and relapses. Further, there is consistency in respect to not only the psychological characteristics of the patients so afflicted but also the particular psychodynamic settings in which the disease is exacerbated or healed.

Ulcerative colitis. A disorder affecting primarily the mucosa and submucosa of the large bowel, ulcerative colitis is characterized by gross bleeding with formed or diarrheal stools when the rectum and sigmoid are involved and by cramps, diarrhea, and occult blood when more proximal colon is involved.

Psychological characteristics. An obsessive-compulsive character structure, sensitivity to rejection or hostility (occasionally approaching paranoid proportions), and a tendency to relate in an intense, dependent, and ambivalent fashion with a limited number of persons are commonly reported psychological features of the ulcerative colitis patient. These characteristics antedate the development of the manifest illness. These people tend to be neat, orderly, punctual, conscientious, stubborn, and often indecisive. They place a high premium on control of affect, tend to intellectualize, and have fairly rigid standards of behavior. Some are petulant, querulous, demanding, and provocative, but well directed self-assertion or expression of aggression is less common. Sensitive and easily hurt, they are constantly alert to and try to ward off or avoid rebuffs, often by being placating, submissive, and polite; by conforming; or by remaining proud, aloof, nonchalant, and haughty. They sometimes give the appearance of great energy, ambition, and efficiency, but this often reflects a need to have palpable accomplishment and to fulfill a sense of obligation in order to overcome feelings of incompetence and inferiority and to satisfy the demands of others.

The patient with ulcerative colitis often reveals a rather consistent pattern of interpersonal relationship, which usually originates in the relationship with the mother. On the one hand, he appears to have a quite dependent relationship on one or two key persons, usually a parent or parent figure; on the other hand, he has a somewhat limited capacity to establish warm, genuine friendships. He uses the key figure as if part of his equipment for dealing with the external world, leaning on him for guidance, advice, and direction. He is reluctant to take the initiative, and he tends to act out the wishes, conscious and unconscious, of the key figure. Yet this is a highly ambivalent relationship, one within which overt expressions of hostility are fraught with great danger, for to be rejected may induce overwhelming feelings of helplessness.

The author has found that the nature of the relationship with the mother is of decisive importance in understanding the psychology of the ulcerative colitis patient. In general, the mothers are controlling and dominating. Both men and women patients are likely to see their mothers as powerful and overwhelming figures, who set exceptionally high standards of performance and make them feel helpless and dependent. Women often describe their mothers as cold, unaffectionate, punitive, rigid, strict, and judgmental; the men are more likely to portray their mothers as kind, considerate women who worry about their well-being.

In general these mothers are either unhappy, pleasureless, gloomy women with no great zest or enjoyment in life or harddriving, businesslike, perfectionistic women who are active and concerned with many outside interests but often dissatisfied with their own or others' accomplishments. They tend to be worrisome, complaining, pessimistic, and often hypochondriacal. Expression of genuine warmth, affection, and understanding comes with difficulty. Many show moderate to severe obsessive-compulsive traits, and a few are psychotic characters or frankly psychotic, usually paranoid. Periods of depression are common. A typical posture of the mother is to assume the role of a martyr, thereby mobilizing guilty reactions from the patient.

The patients usually reveal a high degree of sensitivity to the shifting dynamics of the mother's needs, anxiety, and guilt. They respond to her sigh, disapproving look, or change in posture or facial expression as well as to verbal expressions of distress. Some patients submit passively to the mother's domination; others submit with the complaint that mother won't permit them to do otherwise. In general, the patient feels under great pressure from the mother to perform, whether it be in the sense of general social achievement or to meet the mother's emotional needs or to alleviate her guilt, shame, or anxiety. This may include manipulating others so that the mother will be spared distress. In a word, the patient

learns the conditions under which he will not be rejected. Notable is the need of these mothers to maintain control of their children even after they are adult, often being the ones who contact the doctor or who care for their ill adult offspring, even when spouses are willing and available.

Although the father occasionally plays this role, most often he is the less important parent. The woman patient is likely to portray her father as a gentle, kind, passive, but ineffective man to whom she is quite attached; the man patient is likely to see him as a brutal, punitive, threatening, coarse, and very masculine man who may admire a brother who is more masculine and who more adequately fulfills the father's ideal.

The ulcerative colitis-prone patients tend to gravitate toward work roles and social relationships in which their personality traits are most effective, and indeed some are conspicuously successful in their jobs. Sexual and marital adjustment often present difficulties, first in breaking away from mother and then in finding a suitable replacement for the key relationship. In general, sexual life tends to be less active and interesting, sometimes with an anally tinged aversion leading to such descriptions as dirty and disgusting and to a preoccupation with the possibility of offensive odors. In the choice of a spouse, the qualities of the key figure are often sought, sometimes in the person of the mother-in-law.

Onset. The onset and the exacerbations of ulcerative colitis are reported to occur characteristically in settings in which the key relationship or some symbolic representation thereof is threatened or actually disrupted and the patient, in response, feels helpless to cope with what is happening, often expressed in such terms as "too much," "helpless," "nothing left I could do," "overwhelmed," "despair." Typically such situations may include (1) being called on for performance or achievement which the patient feels incompetent to carry out; (2) disapproval or threat of disapproval from the key figure or surrogate; (3) real, threatened, or phantasied separation from the key figure. Such circumstances may develop very suddenly, in which case the colitis attack may begin within hours or a day or two; or they may occupy a longer period, such as adolescence, during which symptoms gradually or intermittently develop before becoming full blown. Once bleeding, diarrhea, or other organically determined symptoms begin, they are experienced as a profound threat to the patient's strong need to maintain control over his environment, including his own body, and they contribute profoundly to the mounting sense of helplessness and despair.

Nothing is known of the mechanisms involved in the relationship between psychological stress and the activation of ulcerative colitis. The primary site of involvement is the mucosa and submucosa, which show edema and engorgement leading to bleeding and ultimately erosion and ulceration. Although prolonged

administration of parasympathomimetic substances have produced lesions in the gastrointestinal tracts of animals, there is no support for the view that parasympathetic discharge is the primary factor in the pathogenesis of ulcerative colitis. The fact that the affects associated with psychological giving up, namely helplessness and hopelessness, are implicated in the genesis of many organic disease processes suggests a nonspecific relationship between disease predisposition and biochemical or physiological processes associated with these affects. It is of interest that the ulcerative colitis patient experiencing anxiety or rage who remains in control or feels guilt is more likely to develop headache than an exacerbation of colitis.

Ulcerative enteritis. Patients with ulcerative colitis may have similar involvement of the terminal ileum or may develop such a process in the small bowel after colectomy and the establishment of an ileostomy. Attacks characteristically occur under the same circumstances as with ulcerative colitis.

Regional enteritis and granulomatous colitis. Although not the subject of as extensive psychological inquiry as ulcerative colitis, the available data indicate many similarities between patients with regional enteritis or granulomatous colitis and those with ulcerative colitis. Psychologically, the resemblance is greatest in respect to the prominence of anal character traits, the patterns of relating, and the vulnerability to object loss and subsequent development of helplessness as the setting in which onset or relapse of active disease occurs. These similarities are considerable, but they are not yet well enough documented to justify an assumption that the two disorders are identical in respect to all psychological features.

Celiac disease and idiopathic steatorrhea. It is currently believed that celiac disease of childhood and many instances of idiopathic steatorrhea of adulthood represent the same disorder, as evidenced by common histopathological changes and a sensitivity to wheat gluten (gliadin). Further, a large percentage of the adult patients give a history of celiac disorder early in childhood; and proven childhood celiacs, allegedly recovered, may also as adults still show absorption defects, histopathological changes, and reactivity to gluten. Many of the latter have intermittent mild symptoms of malabsorption.

Evidence for a genetic determinant has been brought forth, leading to the suggestion of an inborn enzyme deficiency in the intestinal mucosa as the underlying defect. The natural history of the childhood disease, however, suggests that, although such an underlying mucosal defect and the presence of gluten in the diet may be necessary for the development of the malabsorption syndrome, they are not sufficient, for remissions in the presence of gluten in the diet are well known.

An additional determinant in both children and adults appears to be mediated through psychological

stress. Among children, a disturbance in the mother-child relationship, including changes in patterns of handling and feeding, appear to be associated with exacerbations, and remissions have been brought about through improving the mother-child relationship, even without removing gluten from the diet. Among adults, with and without a childhood history, onset or recurrences are noted in settings in which real or threatened loss of support eventuates in psychological giving up, with feelings of sadness, despair, helplessness, and hopelessness.

Experimental study suggests an interaction among at least three factors in the production of the full blown malabsorption syndrome: the intrinsic intestinal defect, gluten (gliadin) in the diet, and some effect mediated through psychophysiological or neurogenic influences.

Insufficient data are available to justify any statement concerning distinctive psychological characteristics of this group of patients. Many adults with a childhood history of celiac disorder show immaturity, dependency, and unusual vulnerability to loss of love objects. Studies of older children demonstrate the prominence of obsessive-compulsive traits and the controlling and ambivalent nature of the mother's relation with her child. They also point to evidence that such attitudes of the mother antedated the birth of the child. Superficially, these children appear to be passive, often withdrawn, inhibited personalities, for whom overt expressions of aggression or self-assertion seem to be difficult. As infants, they are fussy, irritable, and cry a great deal, even before the onset of the celiac symptoms.

Irritable colon syndrome (spastic colon, mucous colitis). This is the classic functional bowel disorder, characterized by alternating diarrhea and constipation, abdominal cramps, flatulence, and at times increased mucus in the stool. There is much evidence to show that both the typical symptoms and the physiological changes in the colon are the result of parasympathetic influences on the colon and that the colons of these patients react excessively to parasympathetic stimulation as compared to the colons of patients without bowel disorder or with ulcerative colitis, suggesting some intrinsic organic bowel defect, perhaps in innervation. Further, there is almost universal acceptance of the view that bowel symptoms are brought about by psychological influences. Actually, the symptom pattern of this group of patients is by no means restricted to the bowel but includes other expressions of autonomic activity, such as excessive sweating, flushing, dermatographia, lability of pulse, and peripheral vasoconstriction.

From the psychological perspective, these patients are generally noted to be rigid, obsessional, and compulsive individuals who attempt to maintain tight control over their impulses. They tend to be orderly, methodical, conscientious, precise, much preoccupied with cleanliness, tidiness, regularity, punctuality, and schedules. It is not surprising that they gravitate

to work roles in which such qualities are valued, such as accounting, bookkeeping, filing, and library work. They place a high premium on intellectual control and performance and are very restrained in expression of emotions, be they pleasurable or unpleasurable. By the same token, they tend, on the one hand, to maintain a cold, intellectual, almost impervious air toward the emotional turmoil of others and, on the other hand, to be extremely sensitive to hostile or rejecting behavior or emotional outbursts when directed toward them. In this respect they appear hypersensitive and easily hurt to the point at times of paranoid suspiciousness. Especially important in the underlying psychodynamics are conflicts about giving and receiving and the control of aggression. Distrustful and fearful of rejection, especially if aggressive or sexual impulses are displayed, they tend to hold on to what they possess, not to give. Some are notably stingy, stubborn, and parsimonious; others overdo the guise of generosity (reaction formation) but as a result constantly feel unappreciated and disappointed that the recipient is not more grateful. Feelings of depression are common, and there is a relatively high incidence of significant clinical depression, including melancholia.

It has been suggested that the oscillations between constipation and diarrhea so characteristic of these patients reflect shifts between psychologically holding back and maintaining control, on the one hand, and letting go in an unconscious, aggressively soiling or depreciatingly giving way, on the other.

Treatment. From the psychological perspective, the five somatopsychic-psychosomatic conditions discussed above are more notable for resemblances than for differences. In terms of threat to life or serious disability, they may be ranked in the following order: ulcerative colitis, ulcerative ileitis, malabsorption syndrome, regional enteritis, and irritable bowel syndrome, of which only the last may be regarded as without serious risk.

The importance of psychological influences makes it mandatory that a psychotherapeutic attitude characterize the physician who cares for these patients. With the more seriously ill patients, this includes appreciation of the psychotherapeutic implications of being able to bring symptoms under control, whether it be with the aid of steroids or ultimately surgery. In all instances, the role of the physician as a replacement for the lost or threatened key figures in the patient's life is a crucial one. Accordingly, the psychiatrist's most valuable contribution to the care of the sicker patient is in the form of the assistance he gives the medical physician in understanding and utilizing to best advantage his relationship with the patient and in avoiding the sometimes disastrous consequences of a disruption of the relationship. Especially valuable may be the psychiatrist's aid in preparing the ulcerative colitis patient with irredeemable bowel damage to accept ileostomy and colectomy.

Although this approach is predicated on a psychotherapeutically oriented perspective, some patients

can profit from more systematic psychotherapy. The capacity of a patient to so benefit must be evaluated by the psychiatrist, but care must be exercised that the referral, even when initiated by the patient, is not interpreted by the patient as a rejection by the internist or gastroenterologist. The latter, by all means, should maintain an active involvement with the patient so that beginning psychotherapy is seen as an addition, not a loss.

In recognizing the role of psychotherapy in the treatment of these patients, one should also have very clearly in mind what psychotherapy cannot be expected to accomplish. There is no evidence at the present time that psychotherapy, no matter how intensive, can eliminate the biological defect underlying colitis, ileitis, or malabsorption syndrome; therefore, an expectation of complete cure is unjustified. Although remission and complete healing are common, psychotherapy cannot insure against recurrence in the face of sufficient stress.

The major contribution that psychotherapy can make is the modification of the basic psychological structure so as to render the individual less vulnerable to the types of situations in which the disease becomes manifest. These particularly concern the capacity of the patient to develop human relationships and to tolerate their loss or threat of loss. Successful psychotherapy usually brings about a significant improvement in the patient's techniques of dealing with the early parental figures and some resolution of early conflicts. With this, one generally sees a gradual emancipation from parental figures and an increasing capacity to establish satisfying and enduring relationships with others.

As with anyone, however, there may still occur events in the person's life with which he has no effective means of coping, and under such circumstances the disease may resume. In general, the patient who has achieved some successful psychotherapeutic response has more chance of maintaining a remission. But it is of the utmost importance that the patient embarking on psychotherapy clearly understand that psychotherapy cannot eliminate the potential for the organic disease; otherwise, even a mild relapse may be felt as a personal failure or destroy the patient's confidence in the therapist, thereby constituting a major stress capable of provoking a massive recurrence. Many of the serious relapses during or after termination of psychotherapy or psychoanalysis have been of this nature and have led to an unjustified pessimism as to the effectiveness of this approach.

In brief, the indications for and choice of the type of psychotherapy are based on psychological considerations and not on expectations of eliminating the underlying organic disorder.

30.3 OBESITY

ALBERT J. STUNKARD, M.D.

Definition and Diagnosis

Obesity is a condition characterized by excessive accumulation of fat in the body. It is a convention to view it as present when body weight exceeds by 20 per cent the standard weight listed in the usual height-weight tables. But tissues such as muscle can contribute to significant degrees of "overweight," and so this measure is at times only a rough index of obesity. In the future, diagnosis will probably be based on newer and more accurate methods of estimating body fat. In the meantime, the simplest diagnostic method is still the best, inspection and palpation.
